Results of the search for magnetic monopoles with ANTARES

Réunion du Groupement de Recherche sur les Neutrinos, Paris
29-30/05/2017

J. Brunner I. El Bojaddaini A. Moussa Y. Tayalati

On behalf of the ANTARES collaboration

Magnetic monopoles (MMs)

- **Particles with *one magnetic pole* : the magnetic counterparts of electric charges.**
- **Symmetry in Maxwell's equations**
- **Quantization of the electric charge (Dirac in 1931):**

$$g = k \cdot g_D = k \cdot \frac{e}{2 \cdot \alpha}$$

Magnetic monopoles (MMs)

- **GUT theories : MMs would be created after the Big Bang (during the phase transition of symmetry breaking).**
- **The mass of monopoles could exceed 10^{14} TeV which is energetically impossible to be created when the Universe cooled down.**
- **A motivation to the scenario of inflation**
- **MMs would be accelerated by galactic magnetic fields if their mass :**

$$M \lesssim 10^{14} \text{ GeV}/c^2$$

Synthetic monopoles at the lab !!

Manipulation of a Rubidium gas in a **non-magnetic** state close to absolute 0 temperature !

Creation of a system behaving as a magnetic monopole in the quantum field describing the gas

The ANTARES neutrino telescope

Search for MMs with the ANTARES Neutrino Telescope

- A limit on flux found using 5 years of data (2008-2012)
- Total livetime : 1012 days
- ArXiv:1703.00424

Detection principle

- A neutrino telescope uses the detection of upward-going charged particles as a signature of neutrino interactions in the matter below the detector
- Charged particles emit light under a characteristic angle when passing through a medium if their velocity exceeds the speed of light in the medium

Magnetic monopole interaction when crossing the Earth

- The ANTARES telescope is sensitive to up-going particles because of the large amount of background produced in the atmosphere.
- The stopping-power defined by S. P. Ahlen has been used to estimate the energy loss of a monopole when crossing the Earth.
- Despite the high energy loss, magnetic monopoles would remain relativistic and detectable if $M \gtrsim 10^{10} \text{ GeV}/c^2$

$$10^{10} \text{ GeV}/c^2 \lesssim M \lesssim 10^{14} \text{ GeV}/c^2$$

The number of photons produced

The total number of Cherenkov photons with wavelengths between 300 and 600 nm that are directly produced per cm length by a magnetic monopole, delta-rays with Mott and KYG cross section models and by a minimum ionizing muon, as a function of β

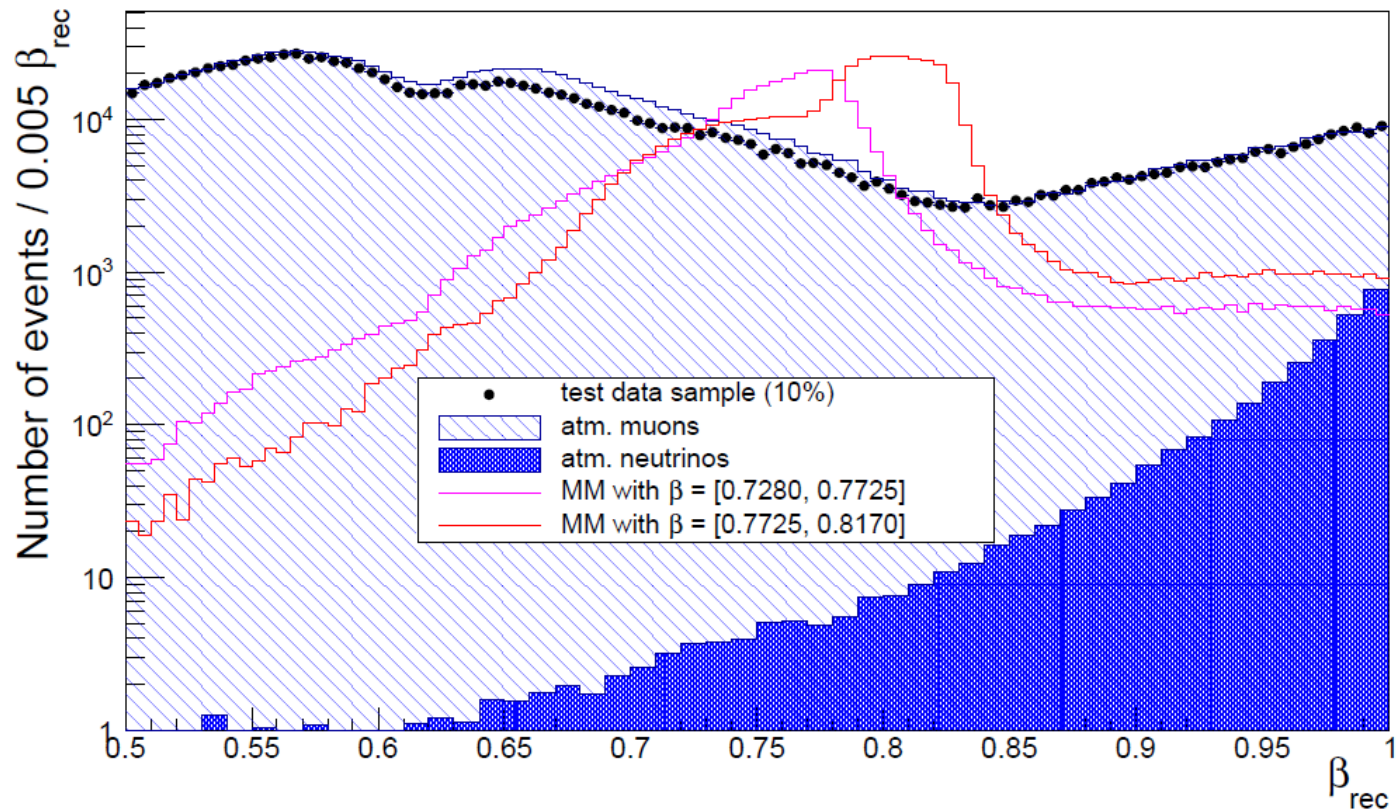

MC simulation & reconstruction

- MMs are simulated with 9 equidistant ranges of velocity in the interval $\beta = [0.5945, 0.9950]$.
- The main source of background :
 - 1- Up-going muons induced by atmospheric neutrinos
 - 2- Down-going atmospheric muons wrongly reconstructed as up-going.
- The analysis is based on a run-by-run Monte Carlo simulation which takes into consideration the real data taking conditions of the detector.

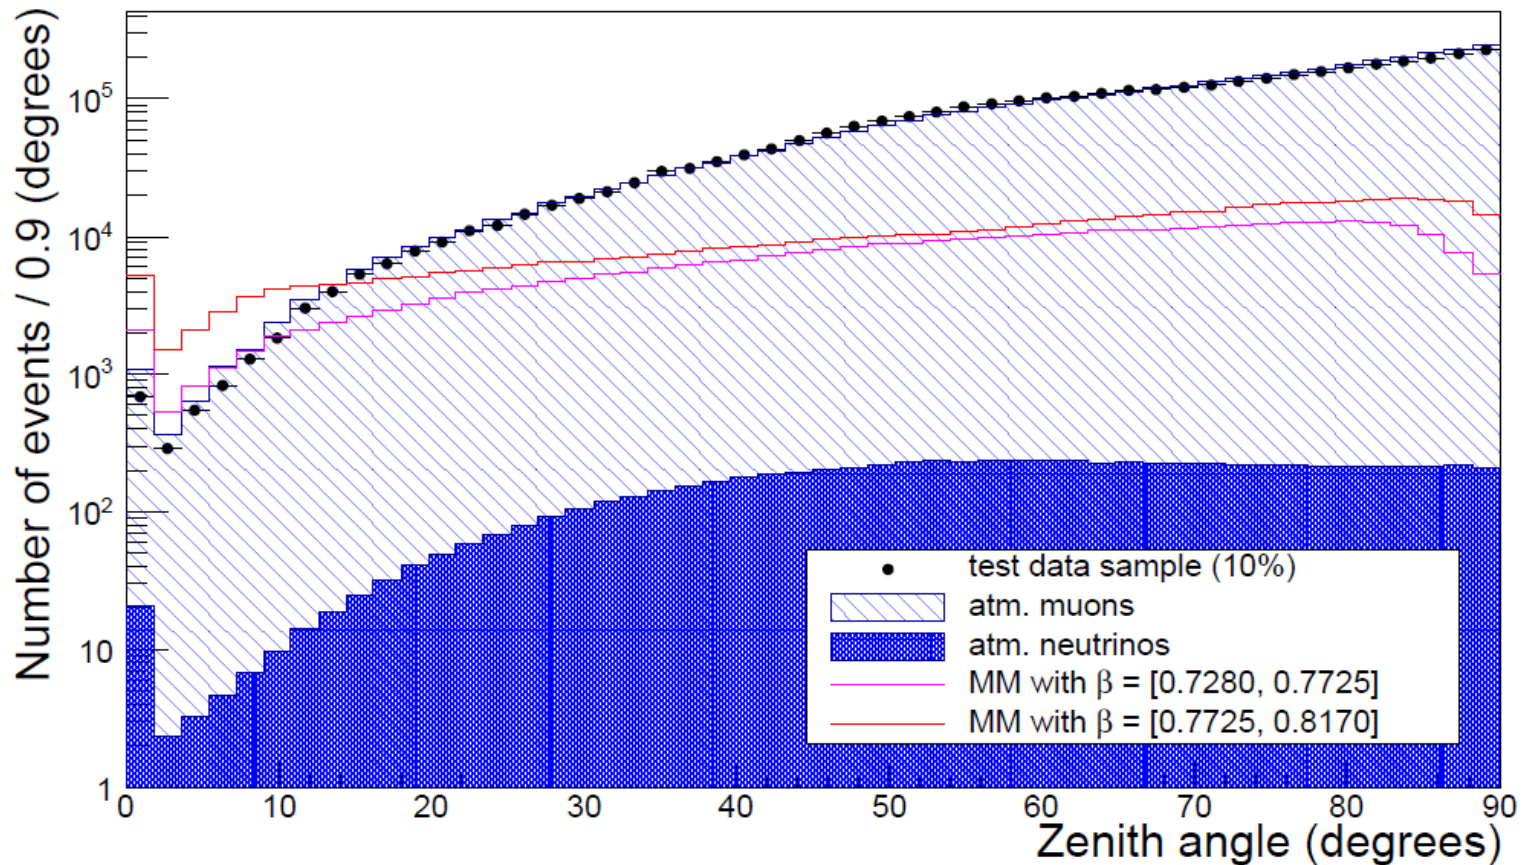

MC simulation & reconstruction

- β is used to distinguish monopoles at low velocities.
- A sample of data (10%) is used for comparison.

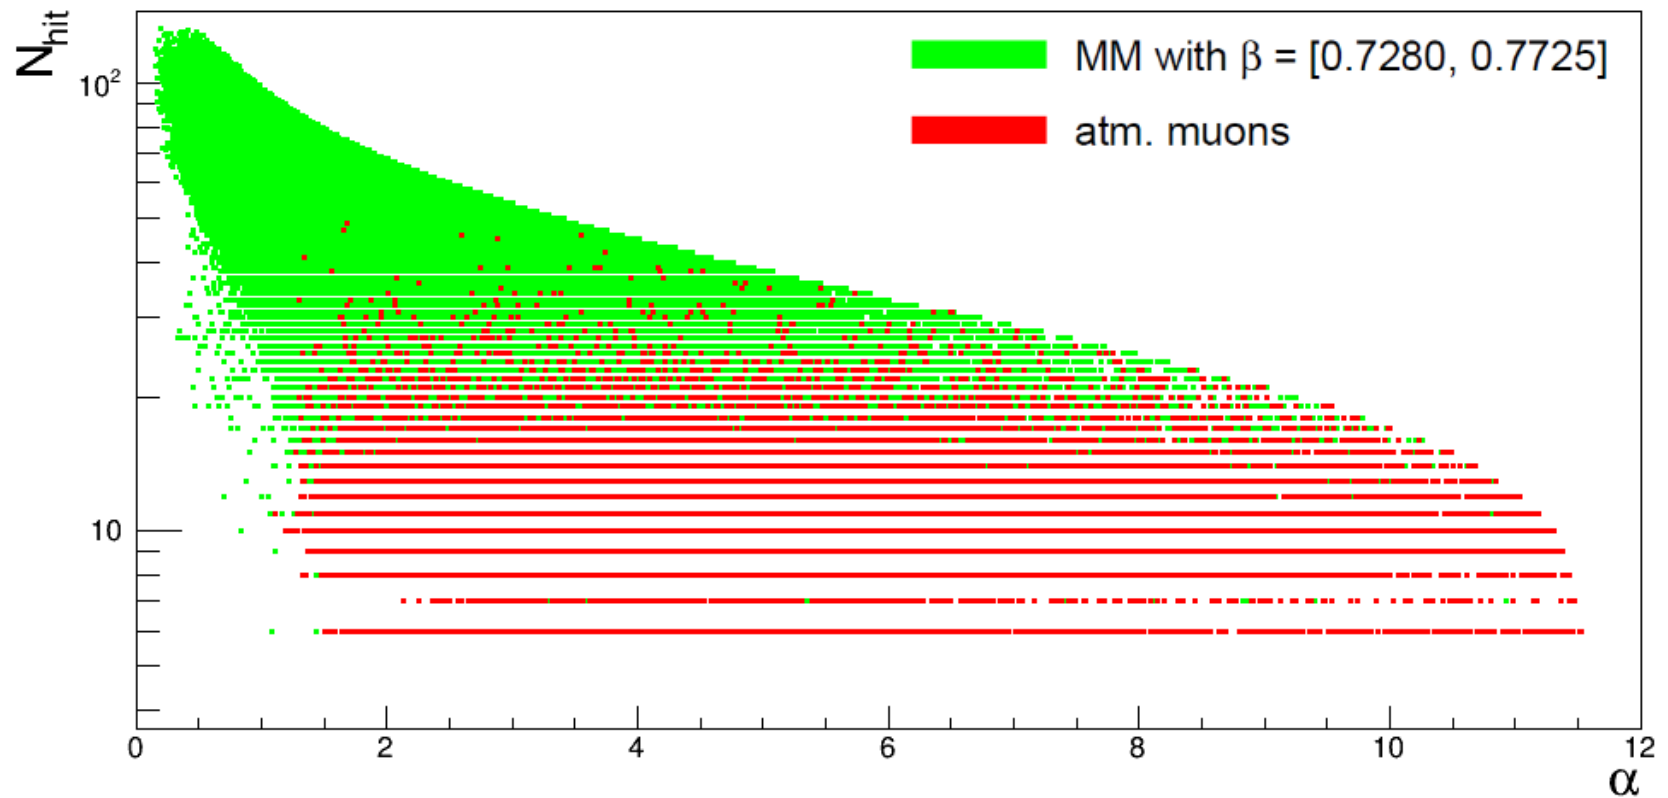

Event selection

- Only up-going events with Zenith $\leq 90^\circ$ are selected
- Despite quality cuts, the selected event sample remains dominated by atm. muons for low beta

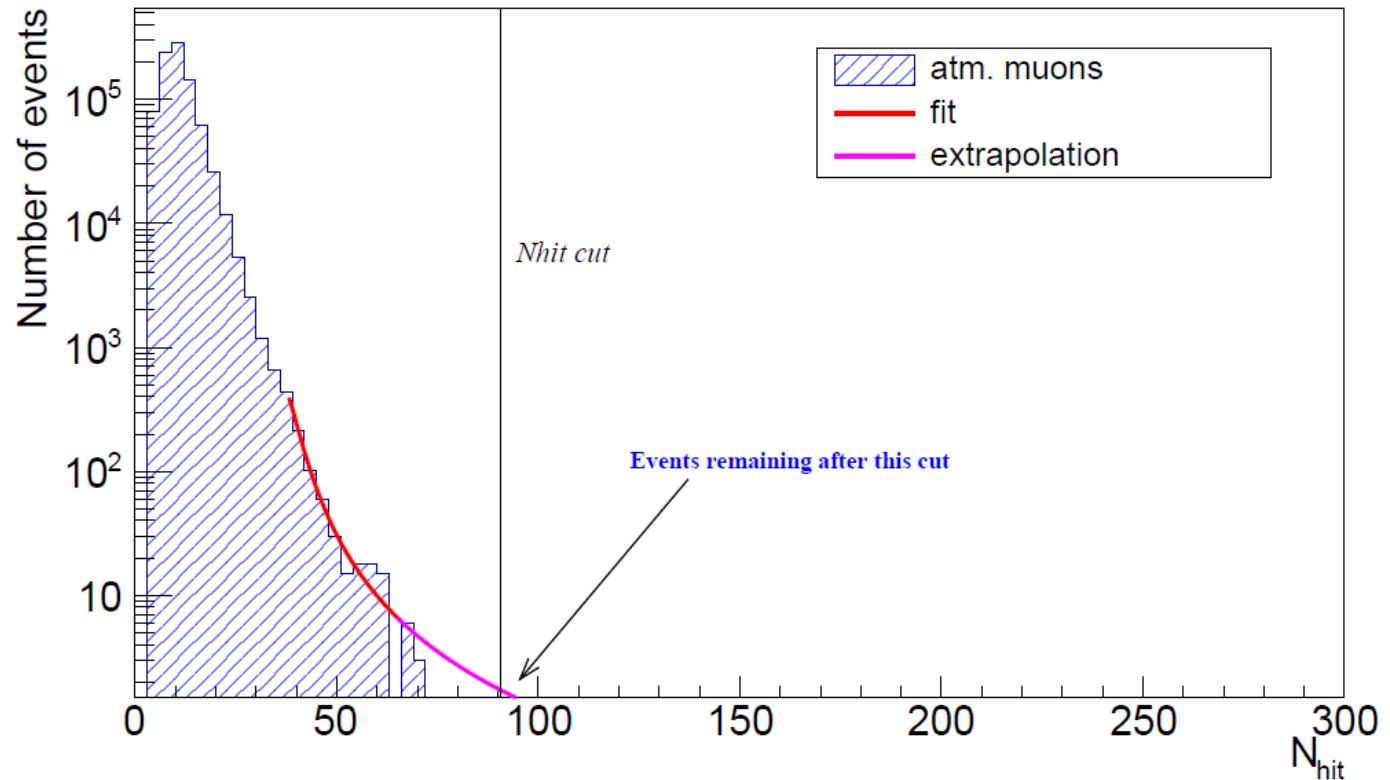

Optimization of cuts

- **N_{hit}** : Number of storeys with a selected track hit.
- **Alpha** : Ratio of track fit quality parameter and N_{hit}.

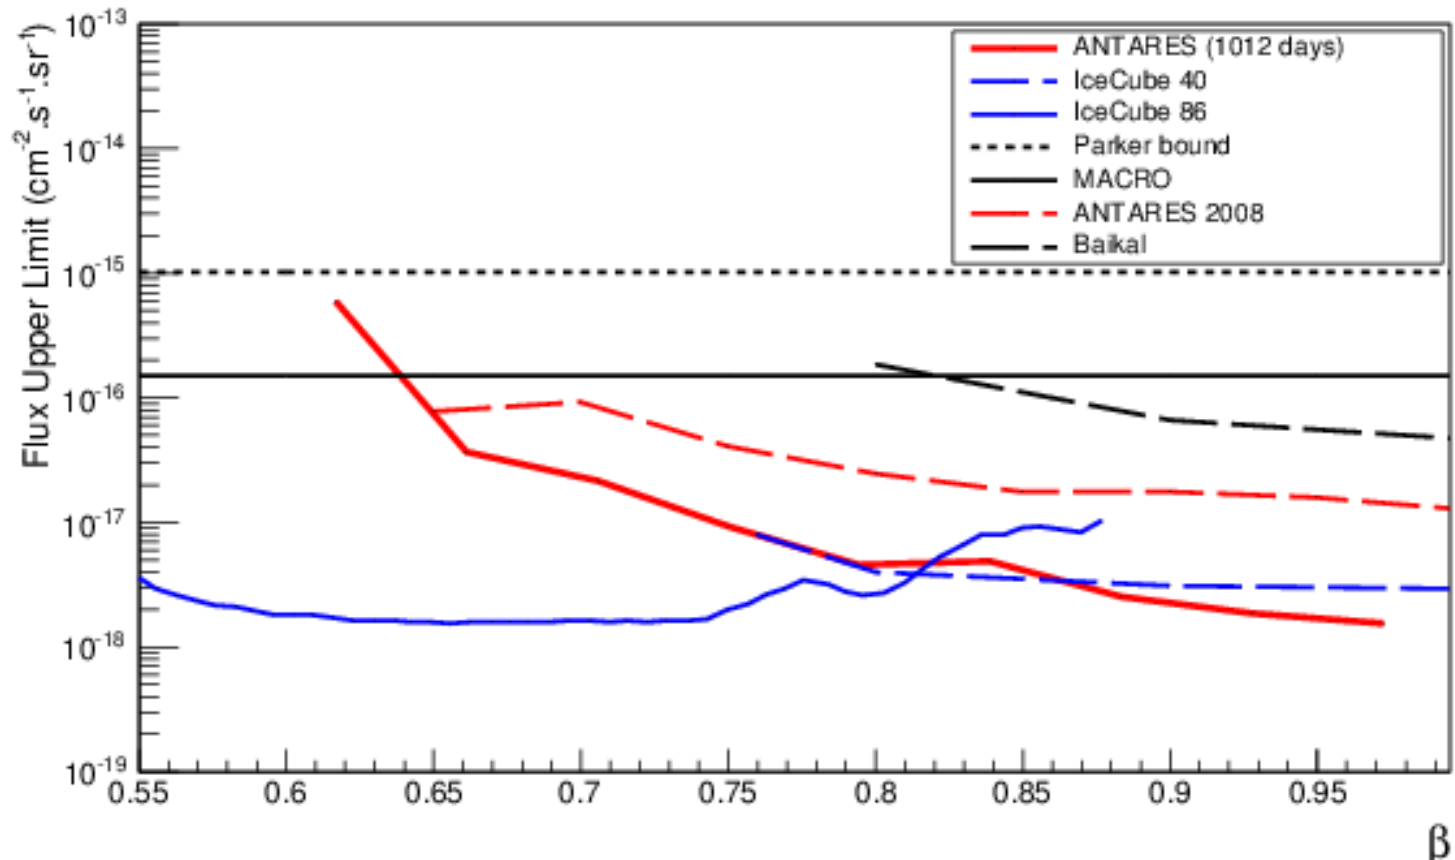

Atmospheric muon background

To compensate the lack of statistics, an extrapolation of N_{hit} distribution is performed.

90 % C.L. upper limits on flux

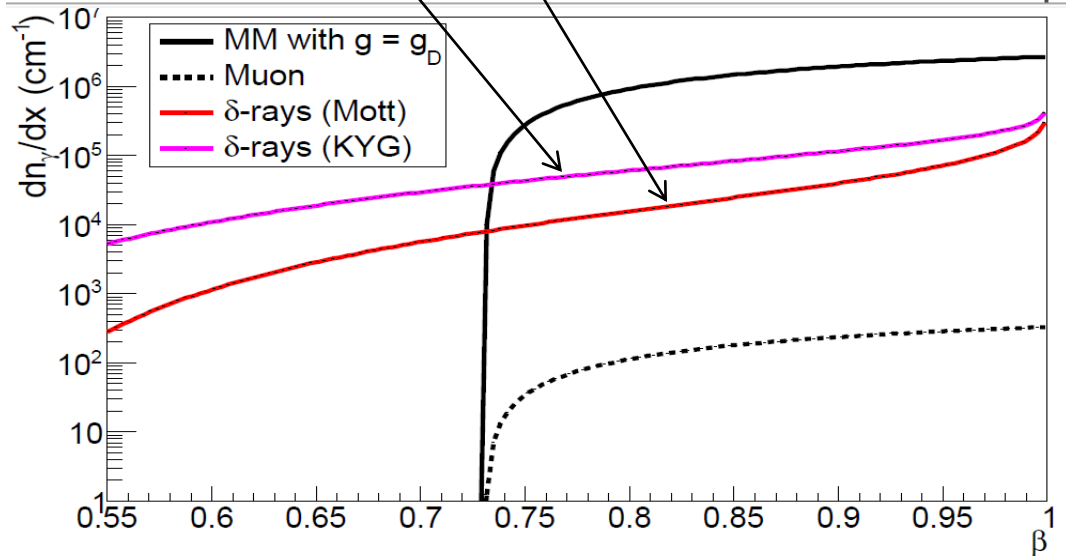

- The 90% confidence interval defined by the Feldman-Cousins approach is used.
- No events observed above the atmospheric background expected.
- **Difficult comparison with IceCube:** Use of a different model of cross section for the production of **delta-rays**.

Conclusion

➤ Below the Cherenkov threshold $\beta=0.74$, the Mott mechanism is used for the production of delta-rays.

➤ Looking forward to use the KYG mechanism that provides more light for monopoles at low velocities.

**A network of DOMs distributed over a large volume
of several KM³**

~ 3000 m of
