## Search for the $B^+ \rightarrow K^+ \nu \bar{\nu}$ decay in the Belle II experiment

**Abstract:** This thesis describes the first search for the decay of a charged  $B$ -meson into a charged kaon and a pair of neutrinos using a hadronic tagging method at the Belle II experiment, operating at the asymmetric electron-positron collider SuperKEKB located at KEK, Tsukuba, Japan. The  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay operates, at the quark level, through a  $b \rightarrow s \nu \bar{\nu}$  flavour changing neutral-current transition. This decay has never been observed due to the experimental challenge posed by the undetected pair of neutrinos in its final state. However its branching fraction is predicted with accuracy in the Standard Model of particle physics, thus, a precise measurement of this branching fraction offers a unique opportunity to probe beyond Standard Model contributions.

The analysis described therein makes use of the Full Event Interpretation algorithm (FEI), developed by the Belle II collaboration to sequentially reconstruct the most probable decay of the  $B_{tag}$  meson accompanying the signal meson  $B_{sig}$  in  $\Upsilon(4S) \rightarrow B_{sig} B_{tag}$  events. The analysis exploits a data sample corresponding to an integrated luminosity of  $362 \text{ fb}^{-1}$  collected at the  $\Upsilon(4S)$  resonance mass, completed by a sample of  $42 \text{ fb}^{-1}$  collected 60 MeV below said resonance.

Given this dataset, the expected upper limit on the branching fraction of  $B^+ \rightarrow K^+ \nu \bar{\nu}$  is determined to be  $2.3 \times 10^{-5}$  at 90% confidence level, using simulated events and data collected in specific control channels. This measurement is expected to be competitive with previous measurements performed by the BaBar and Belle experiments with on-resonance datasets of  $421 \text{ fb}^{-1}$  and  $711 \text{ fb}^{-1}$  respectively.

Furthermore, the development of an algorithmic method to improve the Belle II Silicon Vertex Detector (SVD) resolution on position is presented. This method corrects charge sharing effects between silicon strips in the detector, allowing to improve the spatial resolution for specific sensors by 5 to 15%.

## Recherche de la désintégration $B^+ \rightarrow K^+ \nu \bar{\nu}$ au sein de l'expérience Belle II

**Résumé:** Cette thèse décrit la première recherche de la désintégration d'un méson  $B$  en un kaon chargé et une paire de neutrinos en utilisant une méthode de reconstruction hadronique du  $B$  compagnon au sein de l'expérience Belle II, auprès du collisionneur électron-positon asymétrique SuperKEKB situé à KEK, Tsukuba au Japon. La désintégration  $B^+ \rightarrow K^+ \nu \bar{\nu}$  opère, au niveau des quarks, à travers une transition de courant neutre à changement de saveur  $b \rightarrow s \nu \bar{\nu}$ .

Cette désintégration n'a jamais été observée en raison du défi expérimental posé par la paire de neutrinos non détectée dans son état final. Cependant son rapport d'embranchement est prédit avec précision dans le modèle standard de la physique des particules, la mesure de ce rapport d'embranchement offre donc une opportunité unique de sonder les limites du Modèle Standard. L'analyse décrite ici tire partie de l'algorithme de *Full Event Interpretation* (FEI), développé par la collaboration Belle II pour reconstruire séquentiellement la désintégration la plus probable du méson  $B_{tag}$  accompagnant le méson signal  $B_{sig}$  dans les événements de type  $\Upsilon(4S) \rightarrow B_{sig} B_{tag}$ . L'analyse exploite un échantillon de données correspondant à une luminosité de  $362 \text{ fb}^{-1}$  collectée à l'énergie de la résonance  $\Upsilon(4S)$ , complétée par un échantillon de  $42 \text{ fb}^{-1}$  collecté 60 MeV en dessous de ladite résonance.

Compte tenu de cet ensemble de données, la limite supérieure attendue du rapport d'embranchement de  $B^+ \rightarrow K^+ \nu \bar{\nu}$  est déterminé comme étant  $2.3 \times 10^{-5}$  à un niveau de confiance de 90 %, en utilisant des échantillons d'événements simulés ainsi que des données collectées pour des canaux de contrôle spécifiques. Cette mesure attendue est compétitive avec les mesures précédentes effectuées par les expériences BaBar Belle avec des ensembles de données de  $421 \text{ fb}^{-1}$  et  $711 \text{ fb}^{-1}$  respectivement. Par ailleurs, le développement d'une méthode algorithmique pour améliorer la résolution spatiale du détecteur de vertex à pistes de silicium (SVD) de Belle II est présentée. Cette méthode corrige les effets de partage de charge entre les pistes de silicium dans le détecteur, permettant d'améliorer la résolution spatiale des modules de détection de 5 à 15 %.

# Introduction

1

2 In the second half of the  $XX^{th}$  century, a succession of theoretical works [1–7] trying  
3 to make sense of numerous experimental observations [8, 9] ultimately resulted in  
4 what is now the Standard Model (SM) of particle physics. The SM is a theoretical  
5 framework used to describe elementary particles and their interactions and has been  
6 extensively tested since its inception. It proved to be extremely accurate as well as  
7 capable to predict experimental results [10–13] culminating in the discovery of the  
8 Higgs boson by the ATLAS and CMS experiments at CERN in 2012 [14, 15].

9

10 However, despite this success, the SM fails to be a theory of *everything*. While  
11 describing 3 of the 4 fundamental interactions observed in the Universe, it does not  
12 include a description of gravity and fails to explain the observed asymmetry between  
13 matter and antimatter, as well as the origin and constituents of Dark Matter (DM),  
14 an unknown type of matter which existence can be inferred by their gravitational  
15 effect in astronomical observations [16–19]. In addition, recent experimental results  
16 seem to exhibit tensions with expected SM values [20–22].

17

18 Amongst the physical processes showing tensions with the standard model, the  
19 Flavour Changing Neutral Current (FCNC)  $b \rightarrow s$  quark transitions are of particular  
20 interest. Indeed, several models proposed to expand the SM expect modifications  
21 of these processes from New Physics (NP), which are new particles or interactions  
22 not described by the SM.

23

24 Observations in  $b \rightarrow s\ell^+\ell^-$  seemed to hint towards significant deviations with  
25 the SM and have (at least partially) motivated and justified numerous studies of  $B$ -  
26 mesons decays. However, recent re-evaluations of these  $b \rightarrow s\ell^+\ell^-$  observations [23]  
27 have seen said deviation vanish.

28

29 However, of these  $b \rightarrow s$  transitions, the case of  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decays is partic-  
30 ularly interesting. These decays of  $B$ -mesons into a  $K^{(*)}$  meson, a neutrino and  
31 an anti-neutrino happen through  $b \rightarrow s\nu\bar{\nu}$  quark transitions and have never been  
32 observed to this day. This is due to the fact that neutrinos are not directly detected  
33 in collider experiments as well as to the low probability of such  $b \rightarrow s\nu\bar{\nu}$  transitions  
34 to happen via SM processes. These decay could still be sensitive to NP effects while  
35 being compatibles with the recent  $B \rightarrow s\ell^+\ell^-$  observations.

36

37 Because the probability of  $B \rightarrow K^{(*)}$  decays is precisely known in the SM, a  
38 precise measurement of these processes would allow to identify possible NP contri-  
39 butions and constraint most NP models, advancing towards the goal of a complete  
40 SM.

41

42 In this thesis, we develop a full analysis aimed at the first measurement of  
43 the  $B^+ \rightarrow K^+\nu\bar{\nu}$  decay, using the strengths of the Belle II detector [24] at the  
44 SuperKEKB accelerator [25] which specifically aims at studying such processes.  
45 This document is split into chapters, expanding on the motivations to measure  $b \rightarrow s$   
46 processes, the analysis devised to perform such a measurement as well as additional  
47 work performed as part of the Belle II collaboration. These chapters are organised  
48 as follows:

- 49 • [Chapter 1](#) introduces the main concepts of the Standard Model, and how the  
50 measurement of the  $B^+ \rightarrow K^+\nu\bar{\nu}$  decay can help to better understand it and  
51 constrain contributions from processes beyond the Standard Model.
- 52 • [Chapter 2](#) describes the experimental apparatus used in this work, namely the  
53 Belle II detector and the SuperKEKB collider.
- 54 • [Chapter 3](#) presents work performed in order to improve the performances of  
55 the Silicon Vertex Detector of the Belle II experiment.
- 56 • [Chapter 4](#) describes the analysis techniques and tools used in the search for  
57 the  $B^+ \rightarrow K^+\nu\bar{\nu}$  decay.
- 58 • [Chapter 5](#) presents the strategy aiming at the analysis of data recorded by the  
59 Belle II experiment to measure the branching ratio of the  $B^+ \rightarrow K^+\nu\bar{\nu}$  decay.

As stated in the introduction, the SM successfully explains most of the current experimental observations and has allowed to predict numerous discoveries [10–15]. However it falls short in a theoretical point of view, as it fails to incorporate gravity and neutrino masses as well as providing an explanation for the matter/antimatter asymmetry in the universe. Some recent observations seem to diverge from SM predictions in the  $b \rightarrow sl^+l^-$  [22] and  $b \rightarrow c\tau\nu$  [26–29] transitions. In this chapter we will briefly introduce the SM (Section 1.1) as well as an effective formalism (Section 1.2) which allows to describe the SM as an approximation of a broader theory valid at a specific energy scale. This allows to study  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decays in the SM (Section 1.3) as well as describe several NP scenarios which could affect these decays (Section 1.4). Finally, Section 1.5 will present previous experimental results.

## 1.1 The Standard Model of particle physics

The SM is a theory describing how half-odd spin *fermions* interact with each other through the exchange of integer spin *gauge bosons* that mediate the three fundamental strong, weak and electromagnetic interactions. The 12 fermions (and their 12 corresponding anti-particles) form multiplets of the  $SU(3)_C$ ,  $SU(2)_L$  and  $U(1)_Y$  group components of the local gauge symmetry of the SM:

$$SU(3)_C \otimes SU(2)_L \otimes U(1)_Y \quad (1.1)$$

Where  $SU(3)_C$  corresponds to quantum chromodynamics (QCD) describing the strong interaction and  $SU(2)_L \otimes U(1)_Y$  to the electroweak interaction. All objects

transforming under  $SU(3)_c$  carry a colour charge  $C$  which can take one of three colour values (red ( $r$ ), green ( $g$ ), blue( $b$ )) and/or one of three anti-colour values (anti-red ( $\bar{r}$ ), anti-green ( $\bar{g}$ ), anti-blue ( $\bar{b}$ )). The gluons  $g_i, i \in [1, 8]$  are the gauge bosons mediating the strong interaction, coupling to colour charge while carrying a colour/anti-colour mixture. The gauge bosons  $W_\mu^i, i = 1, 2, 3$  and  $B_\mu$  are associated to the  $SU(2)_L$  and  $U(1)_Y$  factors respectively, coupling to the generator of the associated group (weak isospin  $T$  for  $SU(2)_L$  and weak hypercharge  $Y$  for  $U(1)_Y$ ) with coupling constants  $g$  and  $g'$ .

Through the Higgs mechanism, part of the electroweak gauge symmetry breaks, giving rise to 4 physical boson fields:

$$W^\pm = \frac{(W_\mu^1 \mp iW_\mu^2)}{\sqrt{2}}, \quad Z = -B_\mu \sin \theta_W + W_\mu^3 \cos \theta_W, \quad A = B_\mu \cos \theta_W + W_\mu^3 \sin \theta_W. \quad (1.2)$$

Where  $\theta_W = \tan^{-1}(g/g')$  is the weak angle,  $W^\pm$  are the charged weak boson field,  $Z$  the neutral weak boson field and  $A$  is the photon ( $\gamma$ ) field. The photon couples to the electric charge  $Q = T_3 + \frac{1}{2}Y$ . This symmetry breaking also gives rise to a neutral scalar boson field: the Higgs boson  $H$ .

Fermions can then be divided into two classes depending on their behaviour under  $SU(3)_c$ :

- **leptons** form a  $SU(3)_c$  singlet, meaning they do not interact strongly. There are 3 charged leptons ( $e^-, \mu^-, \tau^-$ ), 3 neutral leptons called neutrinos ( $\nu_e, \nu_\mu, \nu_\tau$ ) and 6 corresponding anti-leptons ( $e^+, \mu^+, \tau^+, \bar{\nu}_e, \bar{\nu}_\mu, \bar{\nu}_\tau$ ). Neutrinos only couple to the weak interaction while charged leptons also couple to the electromagnetic interaction.
- **quarks** are fermions that transform under  $SU(3)_c$ , they couple to the three fundamental interactions of the standard model. There are 6 quarks ( $u, d, c, s, b, t$ ) and 6 anti-quarks ( $\bar{u}, \bar{d}, \bar{c}, \bar{s}, \bar{b}, \bar{t}$ ). Because of the long distance behaviour of QCD, free quarks cannot be observed and spontaneously bind into hadrons (with the exception of the top quark, which spontaneously decays without forming hadrons). The two most common types of hadrons are **mesons** which are formed by a quark and an anti-quark, and **baryons** which are formed by three quarks.

Both leptons and quarks are organised in 3 generations each:

$$\begin{pmatrix} e^- \\ \nu_e \end{pmatrix} \quad \begin{pmatrix} \mu^- \\ \nu_\mu \end{pmatrix} \quad \begin{pmatrix} \tau^- \\ \nu_\tau \end{pmatrix} \quad \begin{pmatrix} u \\ d \end{pmatrix} \quad \begin{pmatrix} c \\ s \end{pmatrix} \quad \begin{pmatrix} t \\ b \end{pmatrix}$$

These come from the way fermions transform under  $SU(2)_L$ : in order to accurately describe the weak interaction, fermions are arranged in weak isospin doublets (*left-handed fermions*, L) and singlets (*right-handed fermions*, R) which are neutral under the weak interaction. These multiplets are:

$$\mathcal{F}_L = \left\{ \begin{pmatrix} \nu_e \\ e^- \end{pmatrix}_L, \begin{pmatrix} \nu_\mu \\ \mu^- \end{pmatrix}_L, \begin{pmatrix} \nu_\tau \\ \tau^- \end{pmatrix}_L, \begin{pmatrix} u' \\ d' \end{pmatrix}_L, \begin{pmatrix} c' \\ s' \end{pmatrix}_L, \begin{pmatrix} t' \\ b' \end{pmatrix}_L \right\}$$

$$\mathcal{F}_R = \{e_R, \mu_R, \tau_R, u'_R, d'_R, c'_R, s'_R, b'_R, t'_R\}$$

125 Because the quark electroweak eigenstates are not the same as the mass eigenstates,  
 126 they are labeled here with primed symbols. In addition, right handed neutrinos are  
 127 not mentioned because they are neutral to all the interactions of the SM and so  
 128 are not SM particles. [Table 1.1](#) lists the particles discussed here as well as their  
 129 properties.

130

The Higgs mechanism introduces Yukawa couplings between the Higgs boson and fermion doublets, producing fermion mass terms. The quark weak eigenstates can be linked to the mass eigenstates by the Cabibo-Kobayashi-Maskawa (CKM) unitary matrix:

$$\begin{pmatrix} d' \\ s' \\ b' \end{pmatrix} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} \begin{pmatrix} d \\ s \\ b \end{pmatrix}$$

131 The coefficients of  $V_{CKM}$  are linked to the transitions between different flavours of  
 132 quarks. The transition from a quark flavour  $i$  to a quark flavour  $j$  being proportional  
 133 to  $|V_{ij}|^2$ . Being unitary,  $V_{CKM}$  needs to verify:

$$\sum_{i \in \{u,d,s\}}^n V_{ij} V_{ik}^* = \delta_{jk}, \quad \sum_{j \in \{u,d,s\}}^n V_{ij} V_{kj}^* = \delta_{ik}. \quad (1.3)$$

134 Where  $\delta_{ij} = 1$  if  $i = j$  and 0 for off-diagonal terms. This is the basis of  
 135 the Glashow-Iopoulos-Maiani (GIM) mechanism, which forbids transitions between  
 136 quark flavours of same electric charge, called flavour-changing neutral currents  
 137 (FCNC), at tree level in the SM and suppresses them at higher order. On the  
 138 other hand, leptons weak eigenstates are also mass eigenstates due to the fact that  
 139 right-handed neutrinos do not exist in the SM, meaning that no transition between  
 140 lepton flavours can occur in the SM.

141 In addition, the 6 off-diagonal relations of [Equation 1.3](#) can each be interpreted as  
 142 triangles in the complex plane. Amongst them, the relation:

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0, \quad (1.4)$$

143 is conventionally chosen to draw what is referred to as a unitarity triangle. This  
 144 sum is furthermore reordered as:

$$1 + \frac{V_{td}V_{tb}^*}{V_{cd}V_{cb}^*} + \frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*} = 0, \quad (1.5)$$

145 in order to place the vertices of the unitarity triangle of [Figure 1.1](#) at  $(0,0)$ ,  $(1,0)$   
 146 and  $(\bar{\rho}, \bar{\eta})$  in the complex plane, with  $\bar{\rho} + i\bar{\eta} = -V_{ud}V_{ub}^*/V_{cd}V_{cb}^*$ . The lengths of the  
 147 triangle sides can then be expressed with the CKM matrix elements as:

$$\overline{AB} = \left| \frac{V_{td}V_{tb}^*}{V_{cd}V_{cb}^*} \right|, \quad (1.6)$$

$$\overline{AC} = \left| \frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*} \right|, \quad (1.7)$$

$$\overline{CB} = 1, \quad (1.8)$$

as well as the three angles :

$$\alpha = \arg \left( \frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*} \right), \quad (1.9)$$

$$\beta = \arg \left( \frac{V_{td}V_{tb}^*}{V_{cd}V_{cb}^*} \right) \quad (1.10)$$

$$\gamma = \arg \left( \frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*} \right). \quad (1.11)$$

148 The measurement of the triangle parameters is a long standing goal of particle  
 149 physics, as their values allow to constrain the 4 free parameters of the SM related  
 150 to the CKM matrix.

Figure 1.1: Representation of Equation 1.5 in the complex plane.

151

152 Finally, Table 1.1 lists the different particles of the SM, as well as their physical  
 153 properties. In addition, several composite particles (mesons and baryons) relevant  
 154 to this work are listed as well.

Particle	Symbol	quark content	Spin <sup>parity</sup>	Mass [eV/c <sup>2</sup> ]	Electric Charge
<b>Gauge Bosons</b>					
Photon	$\gamma$	-	1	0	0

Table 1.1: Properties of the elementary particles of the SM

## 1.2 Effective Field Theory formalism

As stated in the introduction, the SM does remarkably well to describe most processes involving elementary particle and has even proven succesful at predicting several experimental observations. However, we know it to be incomplete. The first phase of the LHC [14, 15] showed that the Higgs boson seems to be SM-like and "light", and that there is a mass gap above the current SM spectrum. Indeed, were there particles in the range  $[m_t, \text{TeV}]$  they should have been observed at the LHC.

The limits of the SM described in Section 1.1 lend to believe that the SM is in fact an *effective field theory* (EFT), low-energy limit of a broader theory valid at a higher scale  $\Lambda$ . In that case, working at an energy  $E \ll \Lambda$  does not require to precisely know of the physics at the  $\Lambda$  scale but only to describe it with a set of effective parameters (whose number depends on the wanted accuracy). This in turn allows to work out physics at different energy scales, which is needed in the case of  $B$  meson decays where different scales are involved: the  $b$  quark mass  $m_b \simeq 4$  GeV, the  $W$  boson mass  $M_W \simeq 80$  GeV corresponding to the scale of electroweak processes and  $\Lambda_{QCD} \simeq 1$  GeV the scale at which QCD becomes non perturbative. An effective Hamiltonian can then be built in the form:

$$\mathcal{H}_{eff} = \sum_i C_i(\mu) O_i(\mu). \quad (1.12)$$

Where the coefficients  $C_i$  describing the physics at high energy are called *Wilson Coefficients* and  $O_i$  are all the operators compatible with the symmetries of the system. Here,  $\mu$  is an intermediate scale between the high energy and low energy limits. Specifically, in the case of the weak decay of a hadron, the effective hamiltonian can be expressed as:

$$\mathcal{H}_{eff} = \frac{G_F}{\sqrt{2}} \sum_i^N V_{CKM}^i C_i(\mu) O_i + h.c., \quad (1.13)$$

where  $G_F$  is the Fermi constant such that  $G_F/\sqrt{2} = g^2/8M_W^2$  and h.c stands for Hermitian conjuguate.

## 1.3 The $B \rightarrow K^{(*)} \nu \bar{\nu}$ decays in the Standard Model

Following the framework described in Section 1.2 the effective Hamiltonian describing  $b \rightarrow sll$  transitions (including  $b \rightarrow s\nu\bar{\nu}$ ) is:

$$\mathcal{H}_{eff} = -\frac{G_F}{\sqrt{2}} V_{ts}^* V_{tb} \times \left[ \sum_{i=1}^6 C_i O_i + c_{7\gamma} O_{7\gamma} + c_{8G} O_{8G} + c_{9V} O_{9V} + c_{10A} O_{10A} \right. \\ \left. + C_L^{\nu} O_L^{\nu} + C_L^{\mu} O_L^{\mu} \right] + h.c. \quad (1.14)$$

Where the  $|V_{us}^* V_{ub}|$  term is omitted as the  $t$  quark related term is  $\simeq 50$  times greater. This is the origin of the breakdown of the GIM mechanism at the one-loop

level which causes FCNCs to appear at one-loop level [30]. The operators  $\mathcal{O}_i$  are as described in [31]:

$$\begin{aligned}
\mathcal{O}_1 &= (\bar{s}_i c_j)_{V-A} (\bar{c}_j b_i)_{V-A} \\
\mathcal{O}_2 &= (\bar{s}c)_{V-A} (\bar{c}b)_{V-A} \\
\mathcal{O}_3 &= (\bar{s}b)_{V-A} \sum_q (\bar{q}q)_{V-A} \\
\mathcal{O}_4 &= (\bar{s}_i b_j)_{V-A} \sum_q (\bar{q}_j q_i)_{V-A} \\
\mathcal{O}_5 &= (\bar{s}b)_{V-A} \sum_q (\bar{q}q)_{V+A} \\
\mathcal{O}_6 &= (\bar{s}_i b_j)_{V-A} \sum_q (\bar{q}_j q_i)_{V+A} \\
\mathcal{O}_{7\gamma} &= \frac{e}{8\pi^2} m_b \bar{s}_i \sigma^{\mu\nu} (1 + \gamma_5) b_i F_{\mu\nu} \\
\mathcal{O}_{8G} &= \frac{g}{8\pi^2} m_b \bar{s}_i \sigma^{\mu\nu} (1 + \gamma_5) T_{ij}^a b_j G_{\mu\nu}^a \\
\mathcal{O}_{9V} &= (\bar{s}b)_{V-A} (\bar{\ell}\ell)_V \\
\mathcal{O}_{10A} &= (\bar{s}b)_{V-A} (\bar{\ell}\ell)_A \\
\mathcal{O}_L^\nu &= (\bar{b}s)_{V-A} (\bar{\nu}\nu)_{V-A} \\
\mathcal{O}_L^\ell &= (\bar{b}s)_{V-A} (\bar{\ell}\ell)_{V-A}
\end{aligned} \tag{1.15}$$

181 In the case of  $b \rightarrow s\nu\bar{\nu}$  transitions,  $\mathcal{O}_L^\nu$  is the sole contributing operator. The  
182 corresponding dimensionless Wilson coefficient  $C_L^{SM}$  is defined as:

$$C_L^{SM} = -X_t/s_w^2, \tag{1.16}$$

183 where  $X_t = 1.468(17)$  the two-loop electroweak corrections to the top-quark contri-  
184 bution to the decay and  $s_w^2 = \sin^2 \theta_w = 0.23126(5)$ , with  $\theta_w$  the electroweak mixing  
185 angle [32]. Thus,  $C_L^{SM}$  is known to a precision of  $\mathcal{O}(1\%)$ .

186 From there, the total branching fraction of the  $B \rightarrow K\nu\bar{\nu}$  decay can be derived from  
187 Fermi's golden rule:

$$\mathcal{B}(B \rightarrow K\nu\bar{\nu}) = N\tau_B |\langle K\nu\bar{\nu} | \mathcal{H}_{eff} | B \rangle|^2 \rho, \tag{1.17}$$

with  $N$  a normalization factor,  $\tau_B$  the lifetime of the  $B$  meson and  $\rho$  a phasespace factor.

However, it is more convenient to study the differential  $B \rightarrow K\nu\bar{\nu}$  branching ratio with respect to the squared invariant mass of the neutrino system ( $q^2$ , defined in subsection 5.4.1.5):

$$\frac{d\mathcal{B}(B \rightarrow K\nu\bar{\nu})}{dq^2} = \frac{(\eta_{EW} G_F)^2 \alpha_{EW}^2 X_t^2}{32\pi^5 \sin^4 \theta_w} \times \tau_B |V_{tb} V_{ts}^*|^2 |\vec{p}_K|^3 f_+^2(q^2) \tag{1.18}$$

Figure 1.2: One-loop (left) and box (right) Feynman diagrams for  $b \rightarrow sl^+l^-$  and  $b \rightarrow s\nu\bar{\nu}$  processes

188 Where  $\alpha_{EW}$  is the fine structure constant evaluated at the  $Z$  boson mass,  $\eta_{EW}$  is a  
 189 short-distance correction factor to  $G_F$  and  $f_+(q^2)$  is a vector form factor described  
 190 in [33–35]. When integrating over the full  $q^2$  range, this gives [36]:

$$\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu}) = (4.43 \pm 0.42) \times 10^{-6}. \quad (1.19)$$

191 From Equation 1.18, one can also derive:

$$\mathcal{B}(B^0 \rightarrow K^0\nu\bar{\nu}) = (4.10 \pm 0.38) \times 10^{-6}. \quad (1.20)$$

With the ratio of the two branching ratios being equal to  $\tau_{B^+}/\tau_{B^0}$ . The value in Equation 1.19 does not take into account the long-distance contribution [37] from the intermediate tau state ( $B^+ \rightarrow \tau^+\bar{\nu}_\tau$  and  $\tau^+ \rightarrow K^+\nu_\tau$ ), which is treated in Chapter 5 as an irreducible background:

$$\mathcal{B}(B^+ \rightarrow K^+\nu_\tau\bar{\nu}_\tau)_{LD} = \frac{|\eta_{EW}G_F|^2 V_{ub}V_{us}^* f_{K^+} f_{B^+}|^2}{128\pi^2 M_{B^+}^3} \times \frac{m_\tau (M_{B^+}^2 - m_\tau^2)^2 (M_{K^+}^2 - m_\tau^2)^2}{\Gamma_\tau \Gamma_{B^+}} \quad (1.21)$$

192 Where  $f_{K^+}$  and  $f_{B^+}$  are the kaon and B-meson decay constants respectively. This  
 193 gives:

$$\mathcal{B}(B^+ \rightarrow K^+\nu_\tau\bar{\nu}_\tau)_{LD} = (6.28 \pm 0.06) \times 10^{-7}. \quad (1.22)$$

Finally, taking into account additional form factors [36], one finds:

$$\mathcal{B}(B^+ \rightarrow K^{*+}\nu\bar{\nu}) = (10.86 \pm 1.89) \times 10^{-6}, \quad (1.23)$$

$$\mathcal{B}(B^0 \rightarrow K^{*0}\nu\bar{\nu}) = (9.05 \pm 1.80) \times 10^{-6}. \quad (1.24)$$

194 The different branching fraction values are subjected to change based on the CKM  
 195 parameters and form factors used in computation (*e.g.* see [35]). The main source of  
 196 uncertainty in Equation 1.19 comes from the form factor  $f_+(q^2)$ . Thus, we further  
 197 develop on how this form factor is computed, which will allow us to accurately

198 estimate its effect on the total uncertainty of our measurement down the line.  
 199 From [38], the form factor can be parametrized using three parameters  $\alpha_0, \alpha_1, \alpha_2$ ,  
 200 such as:

$$f_+(q^2) = \frac{1}{1 - q^2/m_+^2} [\alpha_0 + \alpha_1 z(q^2) + \alpha_2 z^2(q^2) + \frac{z^3(q^2)}{3} (-\alpha_1 + 2\alpha_2)], \quad (1.25)$$

201 with

$$z(t) = \frac{\sqrt{t_+ - t} - \sqrt{t_+ - t_0}}{\sqrt{t_+ - t} + \sqrt{t_+ - t_0}}, \quad (1.26)$$

202 where  $t_{\pm} = (m_B \pm m_K)^2$ ,  $t_0 = t_+(1 - \sqrt{1 - t_-/t_+})$  and  $m_+ = m_B + 0.046$  GeV.  
 203 Using lattice computation valid at high  $q^2$  as well as the light cone sum rules to  
 204 cover the full kinematical region, a fit performed in [35] gives:

$$\boldsymbol{\alpha} = \begin{pmatrix} \alpha_0 \\ \alpha_1 \\ \alpha_2 \end{pmatrix} = \begin{pmatrix} 0.2545 \\ -0.71 \\ 0.32 \end{pmatrix}, \quad (1.27)$$

205 with the associated uncertainty vector  $\boldsymbol{\sigma}$ :

$$\boldsymbol{\sigma} = \begin{pmatrix} \sigma_0 \\ \sigma_1 \\ \sigma_2 \end{pmatrix} = \begin{pmatrix} 0.0090 \\ 0.14 \\ 0.59 \end{pmatrix}. \quad (1.28)$$

206 In addition, to propagate the uncertainties on the value of the  $\boldsymbol{\alpha}$  parameters, we  
 207 compute the covariance matrix  $C_{\alpha}$  of  $\boldsymbol{\alpha}$  from the correlation matrix given in [35] as:  
 208

$$C_{\alpha} = \begin{pmatrix} 1.0 & 0.32 & -0.37 \\ 0.32 & 1.0 & 0.26 \\ -0.37 & 0.26 & 1.0 \end{pmatrix} \quad (1.29)$$

## 209 1.4 Search for New Physics in $b \rightarrow s\nu\bar{\nu}$ transitions

210 This section explains general corrections from NP to the effective treatment of the  
 211  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decays. We then briefly introduce several NP models impacting to  
 212 these decays and show how the measurement of  $\mathcal{B}(B \rightarrow K\nu\bar{\nu})$  allows to constrain  
 213 these models.

214 Considering NP (at energies larger than the B-meson mass), two additional operators  
 215  $C_L$  and  $C_R$  appear in the effective low-energy Hamiltonian of Equation 1.14:

$$\mathcal{H}_{eff} = -\frac{4G_F}{\sqrt{2}} V_{tb} V_{ts}^* (C_L \mathcal{O}_L + C_R \mathcal{O}_R) + h.c \quad (1.30)$$

216 With:

$$\mathcal{O}_R = \frac{e^2}{16\pi^2} (\bar{s}\gamma_{\mu} P_R b) (\bar{\nu}\gamma^{\mu} (1 - \gamma_5)\nu) \quad (1.31)$$

217 It is important to note that LFU of NP is assumed here. It is then possible to define  
218 two real parameters  $\varepsilon > 0$  and  $\eta \in [-\frac{1}{2}, \frac{1}{2}]$ , defined from the Wilson coefficients:

$$\varepsilon = \frac{\sqrt{|C_L|^2 + |C_R|^2}}{C_L^{SM}}, \quad \eta = \frac{-\text{Re}(C_L C_R^*)}{|C_L|^2 + |C_R|^2} \quad (1.32)$$

Thus,  $\varepsilon = 1$  and  $\eta = 0$  in the SM. Deviations would signal the presence of right-handed currents.

The branching ratios of  $B \rightarrow K\nu\bar{\nu}$  and  $B \rightarrow K^*\nu\bar{\nu}$  can then be linked to  $\varepsilon$  and  $\eta$ :

$$\begin{aligned} R_K^\nu &\equiv \frac{\mathcal{B}(B \rightarrow K\nu\bar{\nu})}{\mathcal{B}(B \rightarrow K\nu\bar{\nu})_{SM}} = (1 - 2\eta)\varepsilon^2, \\ R_{K^*}^\nu &\equiv \frac{\mathcal{B}(B \rightarrow K^*\nu\bar{\nu})}{\mathcal{B}(B \rightarrow K^*\nu\bar{\nu})_{SM}} = (1 + \kappa\eta)\varepsilon^2 \end{aligned} \quad (1.33)$$

219 Where  $\kappa$  is a ratio of binned form factors [34]. Thus, the measurement of different  
220  $\mathcal{B}(B \rightarrow K^{(*)}\nu\bar{\nu})$  allows to constrain  $C_L$  and  $C_R$  and quantify hypothetical NP effects  
221 (Figure 1.3).

222 Even though in principle no general constraint on the size of NP effects in  $B \rightarrow K\nu\bar{\nu}$   
223 decays can be gauged from other processes, several models draw a link between  
224  $b \rightarrow s\nu\bar{\nu}$  and  $b \rightarrow sl^+l^-$  transitions, as left-handed neutrinos and charged leptons  
225 are grouped in doublets under the  $SU(2)_L$  gauge symmetry. Thus the disparition of  
226 tensions seen in  $b \rightarrow sl^+l^-$  transitions mentioned in the introduction limits the size  
227 of possible NP effects in  $B \rightarrow K^{(*)}\nu\bar{\nu}$ . However, there are still models in which NP  
228 effects in  $B \rightarrow K^{(*)}\nu\bar{\nu}$  arise without constraints from  $b \rightarrow sl^+l^-$ . These different  
229 cases will be briefly discussed in the next sections.

230

231 In addition, lepton flavour has been thus far neglected because all three neutrino  
232 flavours contribute to  $B \rightarrow K^{(*)}\nu\bar{\nu}$  and they cannot be distinguished experimen-  
233 tally. However in the case of  $b \rightarrow sl^+l^-$  transitions, measurements have only been  
234 performed for  $l = e, \mu$ , with the muon modes providing the most precise results  
235 and the electron modes being less constrained. In addition,  $b \rightarrow s\tau^+\tau^-$  modes  
236 have not been observed at all because of the experimental challenge posed by the  
237 tau-leptons reconstruction. However if NP couples mostly to the third generation  
238 of leptons, large modifications in  $B \rightarrow K\nu\bar{\nu}$  could be seen while being compatible  
239 with  $b \rightarrow se^+e^-$  and  $b \rightarrow s\mu^+\mu^-$  observations.

240

241 Finally, as mentionned before, the experimental apparatuses of current collider  
242 experiments do not allow to detect neutrinos. Thus, the measurement of  $B \rightarrow$   
243  $K^{(*)}\nu\bar{\nu}$  decays actually includes all  $B \rightarrow K^{(*)}+$  invisible modes, with the additional  
244 particles being potential dark matter or SUSY candidates. If such particles were  
245 contributing here, the measured value of the  $B \rightarrow K^{(*)}+$  invisible could be enhanced  
246 while being compatible with  $b \rightarrow sl^+l^-$  observations.

Figure 1.3: Constraints put on the  $C_R$  and  $C_L^{NP}$  Wilson coefficients with combined Belle, BaBar and Belle II measurements (expected at target luminosity  $\mathcal{L} = 50 \text{ ab}^{-1}$ ) of  $B \rightarrow K^{(*)}\nu\bar{\nu}$  observables. The grey areas correspond to 90% confidence level exclusion regions from published measurements of  $\mathcal{B}(B \rightarrow K^{(*)}\nu\bar{\nu})$ . The colored zones correspond to 68% confidence level allowed regions from expected Belle II measurements of  $\mathcal{B}(B \rightarrow K\nu\bar{\nu})$  (green),  $\mathcal{B}(B \rightarrow K^*\nu\bar{\nu})$  (purple) and the longitudinal polarization fraction  $F_L$  of  $B \rightarrow K^*\nu\bar{\nu}$  defined in [34] (orange). Produced using Flavio [39].

### 247 1.4.1 Flavour changing massive neutral boson ( $Z'$ )

248 Modifications to the  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decays can occur through the introduction of an  
 249 additional massive neutral gauge boson, *i.e.*  $Z'$ . Such an addition could significantly  
 250 enhance the decay rate of  $B^+ \rightarrow K^+\nu\bar{\nu}$  by allowing tree-level  $b \rightarrow s$  transitions  
 251 (Subsection 1.4.1). Several  $Z'$  models have been described (see [40] and references  
 252 within), however, the SM-like behavior observed in  $b \rightarrow sl^+l^-$  tends to constrain  
 253 some of them.

254 Still, it is possible to accommodate a  $B^+ \rightarrow K^+\nu\bar{\nu}$  enhancement from  $Z'$  contributions  
 255 with  $b \rightarrow sl^+l^-$  observations, for example by having a light  $Z'$  decaying primarily  
 invisibly, or by requiring a third-generation coupling preference for said boson.

Figure 1.4: Tree-level contribution to  $b \rightarrow s\nu\bar{\nu}$  transitions mediated by a  $Z'$  boson.

256

257 An additional case combines an hypothetical new light neutrino coupling to  
 258 a  $Z'$  boson, described in [41]. However, the number of neutrino flavours  $N_\nu =$   
 259  $2.9840 \pm 0.0082$  [42] is severely constrained by measurements of the invisible  $Z$  bo-  
 260 son decay width at LEP [43] and cosmological constraints. A light sterile neutrino  
 261 interacting with the SM through a  $Z'$  could however exist while contributing only  
 262 marginally to the  $Z$  decay width and  $N_\nu$ , while modifying the values of  $R_\nu^{(*)}$  (see  
 263 Figure 1.5). In addition, this model has the benefit of being unconstrained by  
 264  $b \rightarrow sl^+l^-$  observations.

265

### 266 1.4.2 Leptoquarks

267 Several models introduce leptoquarks (LQ), heavy scalar or vector particles interact-  
 268 ing with both quarks and leptons allowing tree-level FCNC transitions. Numerous  
 269 LQ scenarios have been explored [44–50], while some have been designed to accom-  
 270 modate the previously seen  $b \rightarrow sl^+l^-$  tensions with the SM, numerous others do  
 271 not required such tensions or are even incompatible with them and could thus be  
 272 now reconsidered. These LQ could imply a significant increase of  $\mathcal{B}(B \rightarrow K\nu\bar{\nu})$ , as  
 273 can be seen in Figure 1.6.

Figure 1.5: Correlation between  $R_K^\nu$  and  $R_{K^*}^\nu$  with in blue the allowed region from the model described in [41] showing the increase of the  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decay rates with regard to their SM values.

Figure 1.6: Prediction (best  $1\sigma$  and  $2\sigma$  fit regions) for the predicted  $B \rightarrow K^{(*)}\nu\bar{\nu}$  branching ratio as a function of  $M_L$ , the mass of the vector-like leptons involved the LQ couplings. Orange and purple bands correspond to different coupling values. From [50].

### 274 1.4.3 $B \rightarrow K^{(*)} + \text{invisible}$

275 In addition to adding constraints to models having an effect on  $b \rightarrow s\nu\bar{\nu}$  transitions,  
 276 the measurement of  $\mathcal{B}(B \rightarrow K\nu\bar{\nu})$  allows to indirectly study any NP invisible (=   
 277 weakly or non-interacting) particles. Indeed, as neutrinos are not seen in most parti-   
 278 cle colliders experiments, measuring  $\mathcal{B}(B \rightarrow K\nu\bar{\nu})$  actually boils down to measuring   
 279  $\mathcal{B}(B \rightarrow K + I)$ , with  $I$  being any number of non-detectable particles, including   
 280 neutrinos. In this section, we briefly describe two NP invisible particle candidates.   
 281 QCD axions ( $A^0$ ) are hypothetical bosons introduced to solve the strong CP prob-   
 282 lem [51–54]. They are expected to be very-weakly interacting and light ( $\mu\text{eV} <$    
 283  $c^2 \times m_{A^0} < \text{eV}$ ). Measurements of  $B \rightarrow K\nu\bar{\nu}$  decays allow to impose bounds on   
 284  $B \rightarrow KA^0$  [55].

285 Other pseudoscalar particles sharing similarities with the QCD axion, Axion-Like   
 286 Particles (ALPs), noted  $a'$  are also described, with masses  $m_{a'}$  varying greatly be-   
 287 tween a few MeV and GeV. Searches for ALPs in  $b \rightarrow s$  transitions have already   
 288 been performed in the cases where  $a'$  decay visibly [56, 57].   
 289 Both axions and ALPs could couple to  $W^\pm$  bosons (Figure 1.7) and their invisible   
 290 decays could enhance the  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decay rates.

Figure 1.7: Loop-level contribution to  $b \rightarrow s + I$  transitions from QCD axions  $A^0$  and ALPs  $a'$ .

291

292 Dark matter (DM), the hypothetical weakly interacting matter expected to con-   
 293 tribute  $\sim 25\%$  of the energy density of the universe (to be compared to the  $\sim 5\%$  of   
 294 ordinary matter) [58], can also be constrained by the study of  $B \rightarrow K + I$  decays. In   
 295 particular, a scalar  $S$  with  $m_S \simeq 1 \text{ GeV}/c^2$  [59, 60] could play into a  $B \rightarrow KS$  decay,   
 296 with  $S$  decaying into either a pair of invisible DM fermions or a visible final state   
 297 leaving no signature in the detector (as  $S$  would be long-lived at detector scale).

## 298 1.5 Previous $B \rightarrow K^{(*)}\nu\bar{\nu}$ decay searches

299 As shown in previous sections, the search for  $B \rightarrow K\nu\bar{\nu}$  is strongly motivated and   
 300 has thus been performed several times in the past. However, because of the parti-   
 301 cles escaping detection in the final state of the decays coming from the neutrino pair   
 302 and the SM-expected low branching ratio, such a study proves to be experimentally

Experiment	Year	$\mathcal{L}[\text{fb}^{-1}]$	Method	Mode	Limit at 90% CL	Ref
BaBar	2010	418	SL	$K^+$	$< 1.3 \times 10^{-5}$	[61]
				$K^0$	$< 5.6 \times 10^{-5}$

Table 1.2: Results of previous searches for  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decays, given with the experiment name, year of publication, integrated luminosity of the data sample and method used (SL stands for semileptonic tagging, HAD for hadronic tagging, COM for a combination of the two and INC for an inclusive method).

303 challenging and requires specific instrumentation.

304 To this day, three experiments have attempted to observe  $B \rightarrow K\nu\bar{\nu}$  decays: Belle,  
 305 Belle II and BaBar. All three experiments belong to a type of particle-collider ex-  
 306 periments called B-factories, which will be described in [Chapter 2](#). Belle II is the  
 307 most recent B-factory while BaBar and Belle belong to the previous generation of  
 308 such experiments.

309 Because of the experimental challenge, the previous searches have only allowed to  
 310 set upper limits on the branching ratios of  $B \rightarrow K\nu\bar{\nu}$  decays.

311

312 Studies performed at Belle and BaBar relied on hadronic or semileptonic *tagging*  
 313 described in [Section 4.1](#) while the Belle II search was based on an inclusive method,  
 314 identifying the kaon in the final state of the  $B^+ \rightarrow K^+\nu\bar{\nu}$  decay with the highest-  
 315 momentum track in the event and associating all the remaining information in the  
 316 event to reconstruct the second  $B$ -meson of a  $\Upsilon(4S) \rightarrow B^+B^-$  decay. [Table 1.2](#) and  
 317 [Figure 1.8](#) summarise the results of the previous  $B \rightarrow K^{(*)}\nu\bar{\nu}$  searches.

318

Figure 1.8: Results of previous measurements of the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay by the BaBar, Belle and Belle II collaborations, with the different tagging methods specified (SL stands for semileptonic tagging, Had for hadronic tagging and Inclusive for inclusive tagging).

This chapter presents the experimental setup used in this thesis comprised of the SuperKEKB accelerator and the Belle II detector. [Section 2.1](#) gives a brief description and history of *B-factories*, of which Belle II is the latest iteration. [Section 2.2](#) presents the SuperKEKB accelerator while [Section 2.3](#) describes the Belle II detector. In particular, [Subsection 2.3.2](#) describes the Belle II Silicon Vertex Detector on which the study shown in [Chapter 3](#) has been performed. Finally, [Section 2.6](#) and [2.7](#) present the experiment-specific software tools used in the simulation and reconstruction of collision events.

## 2.1 On B-factories

B-factories are collider particle physics experiments designed to specifically study *B*-mesons (and to some extent  $\tau$ -leptons and *D*-mesons) physics. To produce a large number of *B*-mesons, these experiments rely on collisions between electrons

356 and positrons at the energy of a  $b\bar{b}$  resonance, the  $\Upsilon(4S)$  meson of mass 10.58  
357 GeV/c<sup>2</sup>. The  $\Upsilon(4S)$  has around 100% chance of decaying into a pair of  $B$ -mesons,  
358 with about the same probability of decaying into  $B^+B^-$  and  $B^0\bar{B}^0$  pairs [66].

359 This setup allows for several experimental perks: compared to hadron-hadron col-  
360 lisions (p-p, Pb-Pb), electron-positron collisions produce few particles which eases  
361 event reconstruction. In addition, the four momentum of the  $e^+e^-$  system is known  
362 which allows to reject background and infer the presence of undetected particles  
363 (neutrinos, DM candidates, particles outside the detector acceptance) in the final  
364 state of the event. This proves especially useful in this analysis, where most of the  
365 signal consists of undetected neutrinos.

366

367 The production and study of a large number of  $B$ -mesons is motivated by the  
368 precise measurement of SM processes with the goal of discovering NP. Indeed,  $B$ -  
369 meson decays operate through the weak interaction which possesses interesting prop-  
370 erties (flavour change, CP symmetry violation). In addition, NP might couple more  
371 heavily to third generation fermions, such as  $b$ -quark and  $\tau$ -lepton which further  
372 motivates B-factories physics programs.

373

374 To this day, three specimen of B-factories have been built. The first generation  
375 of B-factories, BaBar and Belle, started collecting data at the end of the 1990s.  
376 BaBar was based in Stanford, USA and has collected 433 fb<sup>-1</sup> of data at the  $\Upsilon(4S)$   
377 resonance provided by the PEP-II accelerator between 1999 and 2008 [67]. Belle  
378 was based in Tsukuba, Japan and has collected 711 fb<sup>-1</sup> of data at the energy of  
379 the  $\Upsilon(4S)$  resonance between 1999 and 2010 using the KEKB accelerator [68]. The  
380 analysis of the data from both experiments is still ongoing [69]. The second gen-  
381 eration of B-factories (*Super* B-factories) consists solely of the Belle II experiment,  
382 direct successor of Belle described in more detail in this section. Belle II started  
383 collecting data in 2019, accumulating until the first half of 2022 a dataset of 424  
384 fb<sup>-1</sup> (see Figure 2.1), out of which 362 fb<sup>-1</sup> have been collected at the  $\Upsilon(4S)$  mass.

385

386 However, B-factories are not the only experiments focused on the study of  $B$ -  
387 meson physics. The LHCb experiment, located at the France-Switzerland border  
388 along the Large Hadron Collider (LHC) studies  $B$ -mesons produced by proton-  
389 proton collisions at an energy of several TeV. This experimental setup makes use  
390 of the large production rate of  $B$ -mesons at high energy at the expense of lower  
391 luminosity and the loss of information on the four momentum of the collision event.

392

## 393 2.2 The SuperKEKB accelerator

394 SuperKEKB is an asymmetric circular electron-positron collider, 3 kilometers in  
395 diameter, operating with an energy around the  $\Upsilon(4S)$  mass. The electron beam is  
396 generated in a pre-injector at the beginning of a linear accelerator (LINAC) and

Figure 2.1: Evolution of the total integrated luminosity recorded by the Belle II experiment before the first long shutdown (LS1).

397 is accelerated to an energy  $E_{e^-} = 7.007$  GeV. The positron beam is obtained by  
 398 irradiating a tungsten target with electrons produced in the pre-injector. Produced  
 399 positrons are then accelerated up to  $E_{e^+} = 4.0$  GeV. Beams are stored in two storage  
 400 rings, the High Energy Ring (HER) for  $e^-$  and Low Energy Ring (LER) for  $e^+$  and  
 401 collided at the interaction point (IP) of the Belle II detector (see [Figure 2.2](#)). The  
 402 energy of the collision in the center of mass (CM) is given by:

$$\sqrt{s} = \sqrt{\left(\frac{E_{e^-} + E_{e^+}}{c^2}\right)^2 - \left(\frac{\mathbf{p}_{e^-} + \mathbf{p}_{e^+}}{c}\right)^2} \approx 10.58 \text{ GeV}/c^2 \quad (2.1)$$

403 Where  $\mathbf{p}_{e^-}$ ,  $\mathbf{p}_{e^+}$  are the three-momenta of the leptons. Because of the asymmetric  
 404 energy of the positron and electron beams, the products of the collision undergo a  
 405 Lorentz boost defined as:

$$\beta\gamma = \frac{\mathbf{p}_{e^-} - \mathbf{p}_{e^+}}{\sqrt{s}} \simeq 0.28 \quad (2.2)$$

406 The energy asymmetry values of the beams are voluntarily set to produce such  
 407 a boost, as it helps identifying the decay vertices of the B mesons, which is especially  
 408 useful in the case of time-dependent CP violation analyses. [Table 2.1](#) shows the  
 409 different physics processes producible with this configuration.

410

411 Even though SuperKEKB uses the same tunnel as KEKB and shares similarities  
 412 in beam energies (8 GeV electron and 3.5 GeV positron beams in the case of KEKB),  
 413 it is expected to reach a luminosity 40 times higher than its predecessor. To reach

Figure 2.2: Schematic view of the SuperKEKB accelerator showing the LINAC, the positron damping ring used to reduce the emittance of positrons, the electron ring (HER) and positron ring (LER). Collision events happen at the Interaction Point located at the heart of the Belle II detector. Taken from [25].

414 this goal, the main improvements to SuperKEKB consist of a twofold increase to the  
 415 HER/LER currents as well as the "nano-beam" scheme which was initially invented  
 416 for the SuperB project [70]. The concept behind this scheme is to reduce the beam  
 417 size at the collision point by a factor of 20 compared to KEKB. The vertical width  
 418  $\sigma_y$  of the lepton bunches is squeezed to a minimal value of  $\simeq 50$  nm, which results  
 419 in the "hourglass effect" where the minimal value is only reached in a small region  
 420 along the  $z$  axis corresponding to the beam direction. To counter this, the hori-  
 421 zontal half crossing angle is set to 41.5 mrad (compared to 11.5 mrad at KEKB).  
 422 This allows to drive the instantaneous luminosity  $L$  which depends on  $x$  as  $L \sim 1/\sigma_x^2$ .  
 423

424 However, the higher currents and reduced beam size give rise to more machine-  
 425 induced background (beam-gas and Touschek scattering, synchrotron radiation, two  
 426 photon QED pair production and radiative Bhabha) in the Belle II detector. This  
 427 poses a challenge as the detector design needs to accomodate such harsh condi-  
 428 tions. So far and since the beginning of the run operation (from early 2019 to mid  
 429 2022), the Belle II experiment has recorded  $424 \text{ fb}^{-1}$  of integrated luminosity deli-  
 430 vered at the  $\Upsilon(4S)$  energy by the SuperKEKB accelerator, reaching a maximum  
 431 instantaneous luminosity of  $4.7 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ . This value constitutes the current  
 432 world record, while the targeted nominal value is  $6 \times 10^{35} \text{ cm}^{-2} \text{ s}^{-1}$  (see Figure 2.3).  
 433 SuperKEKB also allows to vary the beam energies, which gives access to collisions  
 434 between the  $\Upsilon(1S)$  and  $\Upsilon(6S)$  energies (9.46 – 11.24 GeV). The Belle II experiment  
 435 thus performs "energy scans" for physics or background characterization studies.

Process	Cross-section [nb]
$e^+e^- \rightarrow Y(4S)$	1.11
$e^+e^- \rightarrow u\bar{u}(\gamma)$	1.61
$e^+e^- \rightarrow d\bar{d}(\gamma)$	0.40
$e^+e^- \rightarrow s\bar{s}(\gamma)$	0.38
$e^+e^- \rightarrow c\bar{c}(\gamma)$	1.30
$e^+e^- \rightarrow \tau^+\tau^-(\gamma)$	0.92
$e^+e^- \rightarrow \mu^+\mu^-(\gamma)$	1.15
$e^+e^- \rightarrow e^+e^-(\gamma)$	300.0
$e^+e^- \rightarrow e^+e^-e^+e^-$	39.7
$e^+e^- \rightarrow e^+e^-\mu^+\mu^-$	18.9
$e^+e^- \rightarrow \gamma\gamma(\gamma)$	4.99

Table 2.1: Cross-sections of the main  $e^+e^-$  collision processes at  $\sqrt{s} = 10.58$  GeV, taken from chapter 4 of [71].

Figure 2.3: Expected evolution of the instantaneous luminosity delivered by SuperKEKB (red) and integrated luminosity (blue), reaching  $50 \text{ ab}^{-1}$  by 2035. From the Belle II collaboration.

## 2.3 The Belle II detector

The Belle II detector (Figure 2.4) follows the typical pattern of a modern particle collider detector: it consists of a slightly asymmetric (to account for the Lorentz boost) barrel-shaped series of sub-detectors completed with backward and forward endcaps. Its specificity lies in the different types of detectors designed specifically for Belle II physics program as well as the need to maintain high performances in spite of the high background levels from the SuperKEKB accelerator. The main Belle II subdetectors (described in the following sections) are:

- The PiXel Detector (PXD), closest to the beam pipe. Consisting of one layer of DEPFET silicon pixel sensors (a second layer is currently - first half of 2023 - being installed). Its excellent spatial resolution assists in the vertex localisation.
- The Silicon Vertex Detector (SVD). 4 layers of double-sided silicon strip sensors are used for tracking, vertex reconstruction and particle identification.
- The Central Drift Chamber (CDC), which occupies a larger volume and has a higher granularity compared to Belle's CDC, used for tracking and particle identification.
- A particle identification (PID) system split in barrel and endcap regions. The barrel region consists of a Time Of Propagation (TOP) detector while the forward endcap region is equipped with the Aerogel Ring Imaging CHerenkov (ARICH) detector. These mainly allow to well distinguish between pions and kaons.
- An electromagnetic calorimeter (ECAL) based on the CsI(Tl) crystals of Belle's calorimeter. These are put under much pressure from SuperKEKB's background and thus faster readout electronics have been chosen to reduce pileup.
- A supraconductive magnet producing a 1.5 T magnetic field to bend the trajectories of charged particles within the detector volume.
- A  $K_L^0$  and muon detector (KLM) made of a sandwich of thick iron plates and resistive plate chambers making up the outermost layer of the Belle II detector.

The full detector is described at length in [24].

Figure 2.4: Schematic view of the Belle II detector. The origin of the Belle II coordinate system is taken as the nominal interaction point. The  $z$ -axis corresponds to the symmetry axis of the solenoid and has a direction close to the electron-beam. The  $x$ -axis is in the horizontal plane and points towards the outside of the accelerator ring while the  $y$ -axis is vertical and points upwards. The polar angle  $\theta$  is defined with regards to the  $z$ -axis and covers the  $[-\pi, \pi]$  interval while the azimuthal  $\phi$  angle is defined in the  $xy$  plane, in the range  $[0, 2\pi]$ . The additional radial coordinate  $r$  supplements the polar angles  $(\theta, \phi)$  to form a spherical coordinate system. Adapted from Belle II collaboration resources.

### 467 2.3.1 The Pixel Detector

468 Because of the higher machine-induced background faced by the Belle II detector,  
469 the choice has been made to add additional layers to the vertex detection system  
470 of Belle II. The Belle detector used to rely solely on a silicon strip vertex detector  
471 close to the interaction point, however, background conditions in this region in the  
472 nano-beam scheme forbid from using silicon strips. Indeed the detector occupancy  
473 (the fraction of channel hit in each triggered event) would get too high in the Belle II  
474 scenario, which prompted the use of a pixelated detector with a higher number of  
475 channels for the innermost layers of the vertex detection system.

476 The PiXel Detector (PXD) consists of two layers of sensors (numbered L1 and L2)  
477 with radii of 14 mm and 22 mm centered around the beam pipe (Figure 2.5). De-  
478 tection modules, each possessing a matrix of  $768 \times 250$  pixels are glued by pairs to  
479 build ladders. The innermost PXD layer is made of 8 ladders and the second layer  
480 is expected to have 12 ladders. At the time of writing only two ladders are installed  
481 in the second layer, the full installation of the PXD is expected to take place in the  
482 near future. The acceptance covered by the sensor is in the range  $17^\circ < \theta < 155^\circ$ .

483

Figure 2.5: Schematic view of the two-layered pixel detector. The grey areas correspond to the DEPFET pixel sensors. The dark blue areas correspond to the sensor mounts. From Belle II PXD group.

484 The PXD sensors are based on the DEPleted Field Effect Transistor (DEPFET)  
 485 technology [72] in which a semiconductor detector combines detection and amplifi-  
 486 cation of signal. Figure 2.6 shows the cross section of a DEPFET sensor. Here, a  
 487 high negative voltage to a  $p^+$  contact on the back side of the device induces the full  
 488 depletion of a n-type substrate. This creates a potential minimum ("Internal Gate")  
 489 where the electrons created by a charged particle passing through the fully depleted  
 490 bulk, while holes drift to the back contact. When the transistor is on, accumulated  
 491 electrons modulate the channel current. To reset charges in the sensor, a  $n^+$  contact  
 492 is put to a positive voltage to empty the internal gate.  
 493 The readout of the sensor takes  $20 \mu\text{s}$  for a full cycle, with 100 ns of downtime per  
 494 cycle.

### 495 2.3.2 The Silicon Vertex Detector

496 Futher away from the beam pipe is the Silicon Vertex Detector (SVD). It is ar-  
 497 ranged in the same geometry as the PXD (concentric layers made of ladders, barrel  
 498 geometry) and together they make up the Belle II VerteX Detector (VXD). Because  
 499 of the larger surface area to cover, and because it is less close to the beam pipe,  
 500 the SVD is equipped with 172 Double Sided Silicon Strip Detectors (DSSD). The  
 501 number of sensors, their sizes, and the number of strips per ladders vary depending  
 502 on the layer (see Table 2.2). In addition layers L4, L5 and L6 possess trapezoidal  
 503 sensors in the forward region of the detectors to cope with the Lorentz boost in-  
 504 duced by the asymmetry of the collisions. These are slanted in order to improve the  
 505 angular acceptance and optimize the incident angle of particles coming from the IP.  
 506 Trapezoidal sensors are thinner than the rectangular sensors making up the rest of

Figure 2.6: Cross-section of a DEPFET sensor. Taken from [24]

Layer number	Ladders/layer	Sensors/layer	Trapezoidal Sensor angle ( $^{\circ}$ )	
3	7	2 (2 smalls)	n/a	
4	10	3 (2 larges + 1 trapezoidal)	11.9 $^{\circ}$	
5	12	4 (3 larges + 1 trapezoidal)	17.2 $^{\circ}$	
6	16	5 (4 larges + 1 trapezoidal)	21.1 $^{\circ}$	
		Small Sensors	Large Sensors	Trapezoidal Sensors
Readout strips P-side		768	768	768
Readout strips N-side		768	512	512

Sensor active area ( $\text{mm}^2$ )		122.90 $\times$ 38.55	122.90 $\times$ 57.72	122.76 $\times$ (38.42 - 57.59)
Sensor thickness		320 $\mu\text{m}$	320 $\mu\text{m}$	300 $\mu\text{m}$
Manufacturer		Hamamatsu	Hamamatsu	Micron

Table 2.2: Features of the SVD setup. Information taken from [73].

507 the detector (300  $\mu\text{m}$  versus 320  $\mu\text{m}$ ). The total geometric acceptance of the SVD  
 508 is also  $17^{\circ} < \theta < 150^{\circ}$ .

509 Because of the relatively low energy of the collisions, particles produced are subject  
 510 to deflection from multiple scattering, thus their tracks cannot be used for precision  
 511 alignment. To do so, high-energy cosmic muons are rather used, but as their rate  
 512 is limited, the SVD is built with an overlap between adjacent sensors in the range  
 513  $8 \sim 10\%$  (depending on layer) to facilitate alignment, at the cost of a slightly in-  
 514 creased material budget.

515 The DSSDs are made of an N-type bulk with high resistivity on which sensing strips  
 516 are implanted with either acceptors or donors depending on the sensor side. The  
 517 side implanted with acceptors is called "u/P-side" while the other side is called  
 518 "v/N-side". The readout strips on the v/N-side are arranged perpendicularly with  
 519 regards to the ones on the u/P-side, allowing to measure the  $z$  and  $\phi$  direction re-

	Belle	Belle II
Radius of inner cylinder (mm)	77	160
Radius of outer cylinder (mm)	880	1130
Radius of innermost sense wire (mm)	88	168
Radius of outermost sense wire (mm)	863	1111.4
Number of layers	50	56
Number of sense wires	8400	14336
Gas mixture	$He - C_2H_6$	$He - C_2H_6$
Diameter of sense wire ( $\mu\text{m}$ )	30	30

Table 2.3: Main parameters of Belle and Belle II drift chambers. Information from [24].

520 spectively.

521 Because of the strong constraints brought by high machine background, readout  
 522 electronics with a fast shaping time is required. APV25 [74] chips, which were ini-  
 523 tially used in the CMS experiment, were chosen for the SVD. The chips consist of  
 524 128 identical channels of low-noise preamplifiers followed by a 50 ns (tunable) shaper  
 525 stage. APV25 are also sufficiently resistant to radiation and can tolerate an ionising  
 526 dose in excess of 30 MRad (10 MRad would suffice for the experimental conditions).  
 527 For each ladder, APV25 chips are installed directly on the sensors, connected by  
 528 flexible printed circuits with a thermal isolation foam in between. All APV25 chips  
 529 are installed on the same side of the sensors and are connected to the strips on  
 530 the other side by flex circuits wrapped around the edge in a scheme called origami,  
 531 referencing the folding action. This design allows to cool all chips using only one  
 532 cooling pipe, thus reducing material budget (Figure 2.7).

533 The first data taking period of Belle II confirms the excellent behaviour of the SVD.  
 534 The strip noise, dominated by APV25 capacitive input load, leads to a satisfactory  
 535 signal-to-noise ratio, which further validates the choice of the origami chip-on-sensor  
 536 scheme. The spatial resolution of the detector is  $10 \sim 15 \mu\text{m}$  for the P-side and  
 537  $15 \sim 30 \mu\text{m}$  for the N-side, with some room for improvement in the reconstruction  
 538 (see Chapter 3). The hit-time resolution is also good, with 2.4 ns on the N-side and  
 539 2.9 ns on the P-side. The hit-time resolution will become crucial when running at  
 540 the nominal SuperKEKB luminosity to reject off-time beam background hits in the  
 541 SVD and maintain good tracking efficiency.

### 542 2.3.3 The Central Drift Chamber

543 The role of the Central Drift Chamber (CDC) is threefold: to reconstruct charged  
 544 tracks and allow to measure their momentum precisely, to provide 3D trigger infor-  
 545 mation for charged particles and to allow to perform particle identification based  
 546 on energy loss within its gas volume. Because de Belle CDC showed great perfor-  
 547 mance and reliability for over ten years, the Belle II CDC design mainly follows the  
 548 structure of its predecessor, with Table 2.3 showing the main parameters of both

Figure 2.7: Top: Layout of an SVD ladder (layer 6). Bottom: APV 25 chips installed on a sensor and flexible pitch adapters (origami scheme). Images from [73].

564 barrel region and the Aerogel Ring Imaging CHerenkov (ARICH) detector is in-  
 565 stalled at the forward endcap of the Belle II detector.

## 566 TOP

567 The TOP consists of quartz radiators (Figure 2.10) arranged in 16 modules around  
 568 the CDC at a radius of 1.24 m. Charged particles crossing the radiators with enough  
 569 velocity produce Cherenkov photons that totally reflect at the interface of the quartz.  
 570 Cherenkov photons are then focused and directed towards micro-channel plate photo  
 571 multipliers (MCP-PMTs) located at the end of the quartz bar. It is possible to relate  
 572 the Cherenkov photon emission angle  $\theta_C$ , to the velocity  $\beta$  of the particle and the  
 573 refraction index of the radiator  $n$  by:

$$\beta = \frac{1}{n \cos \theta_C} \quad (2.3)$$

574 Here  $n = 1.44$  for photons of 405 nm wavelength. It is possible to measure  $\theta_C$  using  
 575 information of the time of propagation of the photons in the radiator. The time  
 576 resolution of the detector is lower than 50 ps, which allows to distinguish between  
 577 kaons and pions, for which the difference of photon arrival time is  $\sim 100$  ps at 2  
 578 GeV/c<sup>2</sup>.

579 To determine the efficiency of the particle identification, the detected photons distri-  
 580 butions are tested against probability distribution functions (PDFs) for each particle  
 581 hypotheses ( $K, \pi, e, \mu, p, d$ ). For the specific case of  $K/\pi$  separation, the TOP  
 performs well with an efficiency of 85% for a 10% pion misidentification rate [76].

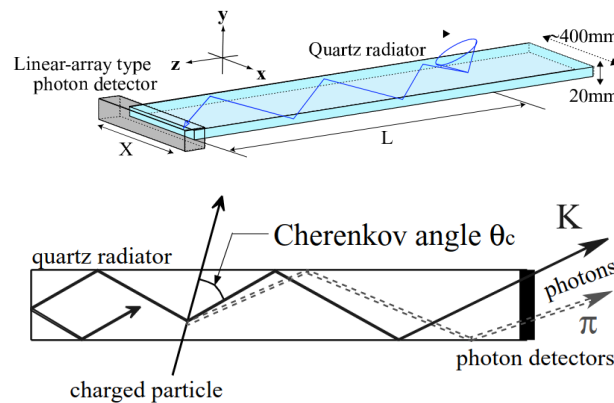

Figure 2.10: Top: Schematic view of a TOP radiator element. Bottom: Side-view showing the working principle of the TOP counter. Image from [24].

582

## 583 ARICH

584 In the forward endcap region of the Belle II detector, the ARICH is used to provide  
 585 separation between kaons and pions over most of the momentum range, as well as

586 discrimination between muons, electrons and pions below  $1 \text{ GeV}/c^2$ . The working  
 587 principle of the ARICH is also based on a measurement of Cherenkov light. Here,  
 588 the radiator is made of a silica aerogel, chosen to be highly transparent in order to  
 589 limit photon loss via Rayleigh scattering or absorption. Two 20 mm thick layers of  
 590 aerogels are used, with refractive indices of 1.055 and 1.065 (these values are chosen  
 591 in order for the Cherenkov rings produced in each layer to overlap on the detection  
 592 plane). After propagating through a 20 cm expansion volume, the produced photons  
 593 are detected by an array of position sensitive photon detectors, Hybrid Avalanche  
 594 Photo Detectors (HAPD), read by integrated circuit chips. The sensors and readout  
 595 electronics were chosen because of their ability to detect single photons in a high  
 596 magnetic field with a good 2D resolution and high efficiency. Figure 2.11 shows a  
 597 schematic view of the detector working principle.

598 The ARICH covers a geometric acceptance in the range  $15^\circ < \theta < 30^\circ$  and performs  
 599 adequately, with a separation efficiency between kaons and pion of 93% with a pion  
 misidentification rate of 10% [77].

600

### 601 2.3.5 The Electromagnetic Calorimeter

602 The Electromagnetic Calorimeter (ECL) is used to detect photons, which is crucial  
 603 in Belle II since one third of  $B$ -meson decays produce  $\pi^0$  and other neutral particles  
 604 that decay into photons, in a wide energy range ( $2 \times 10^{-2} \sim 4 \text{ GeV}$ ).

605 The main calorimeter region consists of 6624 CsI(Tl) pyramidal crystals arranged  
 606 in a 3 m long barrel shape of inner radius 1.25 m. These crystals have an average  
 607 cross section of  $6 \times 6 \text{ cm}^2$  and an average length of 30 cm (corresponding to 16.1  
 608 radiation lengths). This barrel is completed by two endcaps regions, consisting of  
 609 2112 CsI crystals, at  $z_1 = 2.0 \text{ m}$  and  $z_2 = -1.0 \text{ m}$  from the IP (Figure 2.12).

610 This layout provides a geometric acceptance in the range  $12.4^\circ < \theta < 155.1^\circ$ , except

611 for two  $1^\circ$  gaps at the junction of the barrel and endcap regions.  
 612 Each crystal is wrapped in a  $200\ \mu\text{m}$  thick Teflon layer and covered by a sheet of  $25$   
 613  $\mu\text{m}$  thick aluminium and  $25\ \mu\text{m}$  thick mylar.  
 614 For each crystal, two  $10 \times 20\ \text{mm}^2$  glued-on photodiodes are used for scintillation  
 615 light readout. A preamplifier associated to each photodiode produces two independ  
 616 signal outputs for each crystal, these two outputs are then summed in a shaper  
 617 board.  
 618 From performance measurements using cosmic muons, the average output signal for  
 619 the crystals is estimated at  $\sim 5000$  photoelectrons per MeV for a noise level of  $\sim 200$   
 620 keV. The intrinsic energy resolution of the detector can be approximated as:

$$\frac{\sigma_E}{E} = \sqrt{\left(\frac{0.066\%}{E}\right)^2 + \left(\frac{0.81\%}{\sqrt{E}}\right)^2 + (1.34\%)^2} \quad (2.4)$$

621 With  $E$  in GeV.

Figure 2.12: Schematic view of the ECL detector showing the three regions (barrel, and both endcaps). Image from [75].

622

### 623 2.3.6 Solenoid

624 Around the ECL, a superconducting solenoid provides a 1.5 T magnetic field in a  
 625 cylindrical volume 4.4 m in length and 3.4 m in diameter. The main coil of the  
 626 solenoid is made out of a NbTi/Cu superconducting alloy, powered with a 4400  
 627 A current and cooled with a liquid helium cryogenic system. It is used to bend  
 628 the charged particles trajectories to allow the measurement of their momentum. In  
 629 addition, the iron structure of the Belle II detector is used as a return path for the  
 630 magnetic flux.

### 631 2.3.7 The K Long and Muon Detector

632 The outermost part of the Belle II detector is the K Long and Muon detector  
 633 (KLM), which consists of alternating layers of 4.7 cm iron and active detector. The  
 634 iron plates serve as both magnetic flux return for the solenoid and 3.9 radiation  
 635 lengths of material to allow the  $K_L^0$  to shower hadronically. The KLM is composed  
 636 of an octagonal barrel region using Resistive Plates Chambers (RPCs) as detection  
 637 elements and covering a polar angle  $45^\circ < \theta < 125^\circ$ . Two endcap structures car-  
 638 rying scintillator strips coupled with silicon photomultipliers (SiPM), extend the  
 639 acceptance to  $20^\circ < \theta < 155^\circ$ .

640 The barrel region consists of 15 layers of detectors and 14 iron layers, while the  
 641 endcap regions use 14 layers of detectors and 14 iron layers [78].

642 The RPCs are made of two 2 mm glass electrodes planes separated by a 2 mm thick  
 643 plane filled with a 62% HFC-134a (freon 134a), 30% argon and 8% butane-silver.  
 644 High-voltage is distributed along the electrodes using a thin layer of carbon-doped  
 645 paint. Particles going through the gas volume ionize it, generated electrons are then  
 646 collected by metal strips located at the end of the RPCs. These strips are sepa-  
 647 rated from a ground plane by dielectric foam, working as a transmission line with  
 648 a characteristic impedance of  $50 \Omega$ . In order to improve detection efficiency, two  
 649 RPCs are coupled to form a superlayer, with Figure 2.13 showing a structure of a  
 650 superlayer.

651 The endcap regions suffer more from machine background hit rate as they are not  
 652 shielded against neutrons. The use of scintillator detectors in these regions is driven  
 653 by the long dead time of RPCs. The scintillator strips measure up to 2.8 m in length  
 654 and have a cross section of 7 to 10 mm  $\times$  40 mm. In total, the endcaps carry 16800  
 655 of these scintillator strips. Scintillation light is measured by the SiPMs, the whole  
 656 detection system has the advantage of having a good time resolution (around 0.7  
 657 ns) and high output rate.

658 For tracks with a momentum above 1 GeV/c, muon detection efficiency reaches 89%  
 659 for a hadron contamination of 1.3%. The  $K_L^0$  detection efficiency reaches 80% for  
 660 momenta over 3 GeV/c and decreases linearly for lower momentum values.

661

## 662 2.4 Trigger System

663 The Belle II trigger system permits the collection of data for physics events of in-  
 664 terest. The system is designed to perform adequately at the nominal SuperKEKB  
 665 luminosity and must thus satisfy several requirements. Its efficiency for hadronic  
 666 events from  $\Upsilon(4S) \rightarrow B\bar{B}$  and  $e^+e^- \rightarrow q\bar{q}$  must be  $\sim 100\%$  and it should have a  
 667 maximum average trigger rate of 30 kHz to accommodate the expected collision rate  
 668 at nominal luminosity. In addition, the trigger fixed latency should be  $\sim 5$  ns and  
 669 its timing precision be better than 10 ns. The minimum separation power between  
 670 two events should be at least 200 ns.

671 As with much of the detector, Belle II trigger system follows the Belle trigger scheme

Figure 2.13: Cross-section of an RPC superlayer. A KLM module is composed of two superlayers on each side of an iron plate. Image taken from [24].

672 with all components replaced to follow the increased event rate. The trigger scheme  
 673 consists of two tiers: the hardware based Level 1 (L1) trigger uses detector informa-  
 674 tion to remove most of the background while the software-based High Level Trigger  
 675 (HLT), uses reconstructed event information to reduce data as part of the Data  
 676 Acquisition System (DAQ).

677

### 678 Level 1 trigger

679 The L1 trigger is used to reject background events and select events of interest. To  
 680 do so, it harvests raw information from the Belle II subdetectors thanks to sub-  
 681 trigger systems. The information is fed to a Global Reconstruction Logic (GRL)  
 682 which performs a low level reconstruction and sends its output to a centralized  
 683 Global Decision Logic (GDL) which makes the final decision. All the components of  
 684 the L1 possess a Field Programmable Gate Array (FPGA) which allows to configure  
 685 trigger logic.

686 The CDC sub-trigger, which provides information on charged tracks and the ECL  
 687 sub-trigger linked to energy clusters in the calorimeter, are at the root of the L1  
 688 trigger system. The CDC sub-trigger consists of a 2D trigger based on track re-  
 689 construction in the  $(x, y)$  plane, followed by a 3D trigger which allows to estimate  
 690 the  $z$  coordinate of the primary vertex of the event. This allows to reject machine  
 691 background contributions coming away from the IP. The ECL sub-trigger generates  
 692 fast signals based on the total energy deposited in the calorimeter and number of  
 693 clusters for events with both charged and neutral particles. The trigger signals from  
 694 CDC and ECL are then merged with information from the KLM and TOP (Fig-  
 695 ure 2.14) by the GRL and transmitted to the GDL which performs a trigger decision  
 696 based on the output of the different sub-systems.

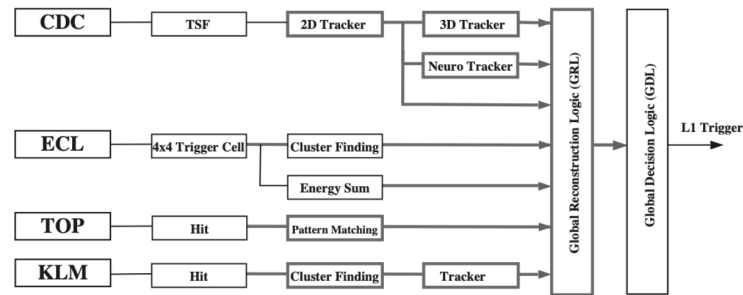

Figure 2.14: Overview of the L1 trigger. Output from the different sub-systems are sent to the GDL which makes the final trigger decision. Image from Belle II trigger group.

697 The L1 output is then fed to the HLT to further refine the selection.

## 698 High Level Trigger

699 The HLT relies on a full, real time reconstruction of the event based on information  
 700 from all detectors but PXD. In order to avoid additional systematic uncertainties,  
 701 the reconstruction software is the one described in Section 2.7, used for offline re-  
 702 construction as well.

703 The software trigger runs on a dedicated server farm and makes the final decision  
 704 of storing or discarding events based on event topology. Furthermore, the physics  
 705 trigger allows to classify events by category (hadronic events, low multiplicity...)  
 706 which is used to restrict the collected data to the processes of interest.

707 In addition, because the PXD possesses a large ammount of pixels, it is impossible  
 708 to perform its full readout for each event. A reduction of PXD data by a factor ten  
 709 is needed before it is combined with other sub-systems. To do so, the HLT extrap-  
 710 olates information from the CDC and SVD to define regions of interest (ROIs) of  
 711 the PXD, for which particle hits are read.

## 712 2.5 The Belle II Analysis Software Framework

713 The Belle II Analysis Software Framework (basf2) [71, 79] is developed and main-  
 714 tained by the Belle II collaboration to provide for the experiment software needs:  
 715 online data processing (as with the HLT), offline reconstruction, physics analysis or  
 716 detector studies. The framework consists of independant *modules* written in C++ [80]  
 717 or `python` [81], which are handled using python steering scripts where they are in-  
 718 tegrated sequentially in *paths*. The number, type and order of the modules used in  
 719 such scripts depend on the task performed. All modules have access to the studied  
 720 data through a common container: the *DataStore*. Additional data that are not  
 721 event-based (calibration, specifics of sub-detectors, etc..) are stored in *conditions*  
 722 and are accessed in a similar container called the *DBStore*.

723 Input and output data analysed with basf2 are usually stored using the ROOT  
724 TTree [82] format.

## 725 2.6 Simulation

726 Monte Carlo (MC) simulation is used to generate physics processes as well as the  
727 interaction between generated particles and the Belle II detector. Cross sections for  
728 the most important physics processes that can occur in  $e^+e^-$  at  $\sqrt{s} = 10.58$  GeV are  
729 given in Table 2.1. Different *generators* are used to simulate base physics processes.  
730 EvtGen 1.3 is used to generate  $B$  and  $D$  mesons decays into exclusive final states [83].  
731 PYTHIA 8.2 [84] models inclusive meson decay final states as well as continuum  $q\bar{q}$   
732 production. KKMC 4.15 generates  $\tau$  pair production while TAUOLA [85] is used to  
733 model  $\tau$  decays. In addition, several generators are used specifically to simulate  
734 QED processes with high cross sections: BABAYAGA [86–90] for  $e^+e^- \rightarrow e^+e^-(\gamma)$  and  
735  $e^+e^- \rightarrow \gamma\gamma(\gamma)$  and AAFH [91–93] for  $e^+e^- \rightarrow e^+e^-e^+e^-$  and  $e^+e^- \rightarrow e^+e^-\mu^+\mu^-$ .  
736 In addition, a specific generator, SAD [94] is used to generate beam background and  
737 produce simulated background hit files.  
738 Finally, the Belle II detector and its interaction with generated particles are simu-  
739 lated using Geant4 [95, 96].

## 740 2.7 Reconstruction

741 Reconstruction is the process through which the enormous amount of raw data  
742 collected independantly by the detectors is transformed into manageable physics  
743 information, in terms of quantity, quality and meaningfulness. After reconstruction,  
744 data are still at a very fundamental stage and can be studied for the benefits of  
745 specific physics analyses, though it does not require an expert knowledge of each  
746 subdetector to make sense.

747 Several algorithms are developed within the basf2 framework by groups working  
748 on each detector, these allow to use low-level objects (detector signal) to produce  
749 higher-level objects (ECL clusters, tracks, etc..).

750 The same reconstruction is applied to both collected raw data and simulation digi-  
751 tized data. For the latter, "true" generated information can be obtained to test the  
752 performance of reconstruction, although this is dependent on how well the process  
753 of interest is simulated.

### 754 2.7.1 Tracking

755 Tracking mostly consists in reconstructing the path taken by charged particles  
756 through the detector. The basic idea is to identify hits from the CDC and VXD  
757 generated by particles of interest amidst background hits and to establish a possible  
758 trajectory from a fit to the hit positions within the magnetic field.

759 Different *track finder* algorithms are used for the tracking detectors as they do not  
760 operate on the same principles nor scales. The common purpose of these algorithms

761 is to identify patterns in detector hits to create track candidates.  
 762 Firstly two track finders are used in conjugation to produce CDC-only track candi-  
 763 dates. CDC track candidates are then linked to SVD clusters using a Combinatorial  
 764 Kalman Filter (CKF). In parralel, tracks that did not reach the CDC due to their  
 765 low momentum (and thus curvature) are reconstructed with the SVD track finder  
 766 using a series of filters of increasing sophistication to avoid high combinatorics [97].  
 767 CDC and SVD track candidates are then combined and extrapolated to the PXD  
 768 with another CKF. Finally, the track is fitted with the GENFIT2 package [98].  
 769 All tracks are fitted with different particle mass hypotheses (pion, kaon and proton)  
 770 to estimate energy loss.

### 771 2.7.2 Charged particle identification

772 Efficient particle identification (PID) is crucial for physics analysis, which is why  
 773 the Belle II detector has benefited from a significant upgrade to its PID system with  
 774 regard to Belle. In addition to the designated detectors (TOP, ARICH), information  
 775 from ionisation ( $dE/dx$ ) measured in the CDC and SVD is used to identify charged  
 776 particles. In addition, energy deposits in the ECL are used to identify electrons  
 777 while the KLM helps to identify muons. Each detector provides a PID likelihood  
 778  $\mathcal{L}_i^{det}$  for each charged particle hypothesis, which is computed independently. These  
 779 likelihoods are then combined to produce an overall likelihood for each hypothesis  $i$   
 780 or  $j$ :

$$\mathcal{L}_i = \prod_{det} \mathcal{L}_i^{det} \quad (2.5)$$

781 This overall likelihood can then be used to compute global PID ratios:

$$PID_i = \frac{\mathcal{L}_i}{\sum_j \mathcal{L}_j} \quad (2.6)$$

782 or binary PID ratios:

$$PID(i|j) = \frac{\mathcal{L}_i}{\mathcal{L}_i + \mathcal{L}_j} \quad (2.7)$$

783 These PID indicators can then be used in physics analyses.

### 784 2.7.3 Neutral particle identification

785 Neutral particles do not ionise materials they pass through, which means that the  
 786 CDC and SVD cannot assist in their identification. Photons are identified using the  
 787 ECL by designing a parameter describing the shower shape of ECL clusters that are  
 788 not matched to any track. Neutral or charged hadron interactions with the ECL  
 789 sometime create hadronic splitoffs, which can mimic photon signatures.

790 Neutral pions are reconstructed in the  $\pi^0 \rightarrow \gamma\gamma$  channel using two photon candi-  
 791 dates. For low energy ( $< 1$  GeV)  $\pi^0$ , the two photons are usually separated enough  
 792 for the ECL showers to not overlap. For pions with energies in the range [1 GeV,  
 793 2.5 GeV], the ECL showers overlap but can still be reconstructed as two separate

794 photons. For  $\pi^0$  with higher energies, the two showers are usually reconstructed as  
795 a single photon candidate, however, the pion's energy can be estimated from the  
796 shower's second moment shape variable.

797  $K_L^0$  identification is done using information from the KLM and ECL. Several mul-  
798 tivariate methods are used to determine if ECL or KLM clusters originate from a  
799  $K_L^0$ . The variables used for this classification are related to kinematics and cluster  
800 shapes as well as the distance between clusters and the closest track and timing  
801 information.

In this chapter we describe how *clusters* are reconstructed from the information collected by silicon strips in the Silicon Vertex Detector (SVD) introduced in [Subsection 2.3.2](#). Furthermore, the resolution on the cluster position is defined in [Section 3.1](#) and the performances of the detector are estimated. Following observations of discrepancies between simulated and measured SVD spatial resolution, and in a general effort to better detector performances, we present an algorithmic method destined to refine the computation of the cluster position resolution. The novel method of *cluster unfolding* is devised to correct for a strip-charge sharing effect seen in recorded data and its effect on spatial resolution performances is estimated in [Section 3.3](#).

## 3.1 Definition of the cluster position resolution

As described in [Subsection 2.3.2](#), the SVD collects information from charged particles crossing detector sensitive volume. The objects used to estimate particle hit-position are called *clusters* and are built from strip information.

In order to be retained to build a cluster, strip signals need to verify:

$$SNR = \frac{S_i}{N_i} > 3 \quad (3.1)$$

Where  $S_i$  is the maximal signal height collected by the strip  $i$  and  $N_i$  is the strip electronic noise.

Figure 3.1: Schematic view of a track crossing a u/p-side SVD sensor. The strips of the sensors (dashed lines) are parallel to the  $v$  local direction. The blue line corresponds to the projection of the track on the  $(\hat{u}, \hat{w})$  plane orthogonal to the strips. The incident track angle  $\theta$  is the angle between the track projection in the  $(\hat{u}, \hat{w})$  plane and the normal vector  $\hat{n}$ , orthogonal to the  $(\hat{u}, \hat{v})$  plane (sensor plane). The local  $v$  direction is parallel to the global Belle II  $\phi$  coordinate, while the local coordinate  $u$  measures the global  $z$  direction.

836 A cluster can be constructed as a collection of any number of contiguous strips  
 837 meeting this requirement in addition to requiring one strip (called *seed* strip) with  
 838  $SNR_{seed} > 5$ .

839 Basic cluster information can be further computed to be used in tracking. The  
 840 cluster charge  $S_{CL}$  is defined as the sum of the individual charges of the strips  
 841 making up the cluster:

$$S_{CL} = \sum_{i=0}^{i < size} S_i \quad (3.2)$$

842 The size of clusters depends mainly on the incident angle  $\theta$  of particle tracks (Fig-  
 843 ure 3.1). The cluster time  $t_{CL}$  is computed as the weighted average (center of gravity  
 844 or CoG) of the strip times:

$$t_{CL} = \frac{\sum_{i=0} t_i \times S_i}{\sum_{i=0} S_i} \quad (3.3)$$

845 With  $t_i$  the time of the strip  $i$ . Finally, the cluster position  $x_{CL}$  is computed from  
 846 the position of the individual strips with the same CoG method:

$$x_{CL} = \frac{\sum_{i=0} x_i \times S_i}{\sum_{i=0} S_i} \quad (3.4)$$

847 With  $x_i$  the local position of the strip  $i$ .

848

849 The cluster position is used by the tracking algorithm described in [Subsec-](#)  
 850 [tion 2.7.1](#), making it a key component of Belle II physics performances. Because of  
 851 that, performance studies on the cluster position resolution need to be performed  
 852 regularly by the collaboration to ensure the quality of tracking.

853 In order to estimate the spatial resolution of the detector, the reconstructed clus-  
 854 ter position should be compared to the true position of the particle crossing the  
 855 detector. Of course this true position is not known, but it can be estimated by  
 856 reconstructing the particle track and extrapolating it on the SVD sensor surface.

857 To this end, it is possible to compute, for each reconstructed track, the *unbiased*  
 858 *track intercept position*, further used as the estimator of the true position of the  
 859 studied cluster. Here, the track reconstructed by the track fitting algorithm using  
 860 clusters from all SVD layers is re-fitted while excluding the cluster of interest. The  
 861 position  $x_t$  at which this track crosses the studied cluster plane is the unbiased  
 862 track intercept position, to which an error  $\sigma_t$  is associated. The distance between  
 863 the measured cluster position  $x_{CL}$  and  $x_t$  is the *residual*  $\varepsilon_t$ . The cluster resolution  
 864  $\sigma_{CL}$  is given by:

$$\sigma_{CL} = \sqrt{\langle \varepsilon_t^2 - \sigma_t^2 \rangle} \quad (3.5)$$

865 The cluster position resolution study is performed both on data and simulation. In  
 866 the case of the latter, the *true* position  $x$  of clusters is also known, as well as the *true*  
 867 cluster position residual  $\varepsilon_m = x_{CL} - x$ , the track true position  $t$  and true residual  
 $\varepsilon_{true} = t - x$ . The definition of these variables is shown in [Figure 3.2](#).

Figure 3.2: Schematic view of the main quantities used in the estimation of the spatial resolution of the SVD.

868

869 Example distributions of the measured residuals, true cluster and track residual,  
 870 and track extrapolation error are shown in figure Figure 3.3 for layer 4 u/P clusters.

Figure 3.3: Distributions of the measured residuals  $\varepsilon_t$  (top left), true cluster residual  $\varepsilon_m$  (top right), track extrapolation error  $\sigma_t$  (bottom left) and true track residual  $\varepsilon_{true}$  (bottom right), for L4U clusters from simulated di-muon events. Adapted from Belle II's SVD group.

871

## 872 3.2 Data/simulation comparison

873 Figure 3.4 shows the resolution for the layer 3 for both detector sides as well as  
 874 the sum of layer 4, 5 and 6 for both sides. The resolutions for data and simulation  
 875 are computed as described in Section 3.1. We see that discrepancies in resolution  
 876 appear between data and simulation. This trend is more pronounced for u/P sides  
 877 than for v/N sides and is clearly noticeable for layer 3 in u/P side.

878 These discrepancies can be caused by several mechanisms. Firstly, the Belle II SVD  
 879 simulation uses a simplified model of data collection and, for example, does not  
 880 take into account effects described by the Shockley-Ramo theorem [99]. In addition,  
 881 electronic effects within the detector may have not been identified during detector  
 882 calibration and may thus not be simulated. This results in an optimistic simulation  
 883 with regards to the estimation of SVD performances on position resolution.

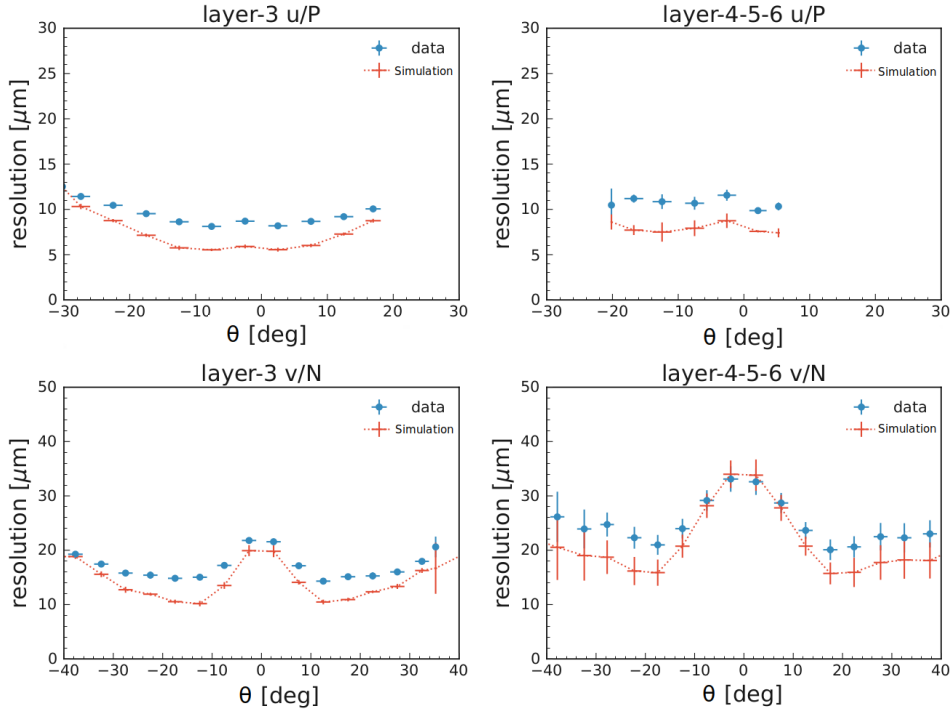

Figure 3.4: Comparison between data and simulation of the cluster position resolution as a function of the track incident angle  $\theta$ .

884 However, the actual detector performances observed in data are extremely satis-  
 885 factory and close to the expected digital resolution of the detector. It then seems  
 886 relevant to point out that the discrepancies observed are expected to be the result  
 887 of a combination of small mechanisms, which are not obvious to identify. Never-  
 888 theless, we try here to identify and correct for these effects, in order to deepen our  
 889 knowledge of the detector and to try and reach optimal performances.

### 890 3.3 The Unfolding Method

891 When, during calibration runs, a charge is injected in one of the APV channels, a  
 892 small signal  $\simeq 5$  ADC count (here, ADC count refers to the output of an Analog  
 893 to Digital Converter and is proportional to the deposited charge) is seen on the  
 894 adjacent channel with a lower peaking time (by  $7/8$  APV clock  $\simeq 27$ ns), showing a  
 895 coupling between the two channels (Figure 3.5). This effect modifies the observed  
 896 strip charge. Preliminary studies show that the observed adjacent strip charge could  
 897 be underestimated by  $\simeq 6\%$  of the seed strip charge.

898 Because the strip charge is used in the computation of the cluster position  $x_{CL}$   
 899 this might degrade the position resolution.

900 In order to correct for this effect, we propose a method aimed at unfolding the strip  
 901 charges in a cluster by extending the coupling effect observed on APV channels to

Figure 3.5: Response curve of an APV channel (purple) to the injection of a MIP-equivalent signal and from its adjacent channel (green) showing a coupling response. Taken from the Belle II SVD software group

902 a whole cluster.

### 903 3.3.1 Design of the Unfolding method

904 In order to model the impact of the APV coupling effect on the charge distribution  
 905 in a cluster, we make the following hypotheses, also schematically explained in  
 906 [Figure 3.6](#):

- 907 1. Each strip in the cluster gives away  $c \simeq 6\%$  of its collected charge to one  
 908 neighbour on each side (for a total loss of 12% of the initial charge).
- 909 2. Edge strips lose  $c \simeq 6\%$  of their charge by exchanging it with strips that do  
 910 not pass the charge threshold to be included in the cluster. This charge is lost  
 911 from the reconstructed cluster.
- 912 3. Edge strips do not gain charge from strips that do not pass the charge thresh-  
 913 old.
- 914 4. These charge exchanges happen simultaneously.

915 To correct these effects and estimate their impact on resolution, the *true* strip  
 916 charges have to be computed from the *observed* strip charges, then, the cluster  
 917 position has to be computed and compared for both sets of charges using the CoG  
 918 algorithm.

919 Because our hypothesis on the behavior of the edge strips, the total charge is not  
 920 expected to be conserved between the *true* and *observed* clusters. In addition, both  
 921 clusters are expected to have the same size.

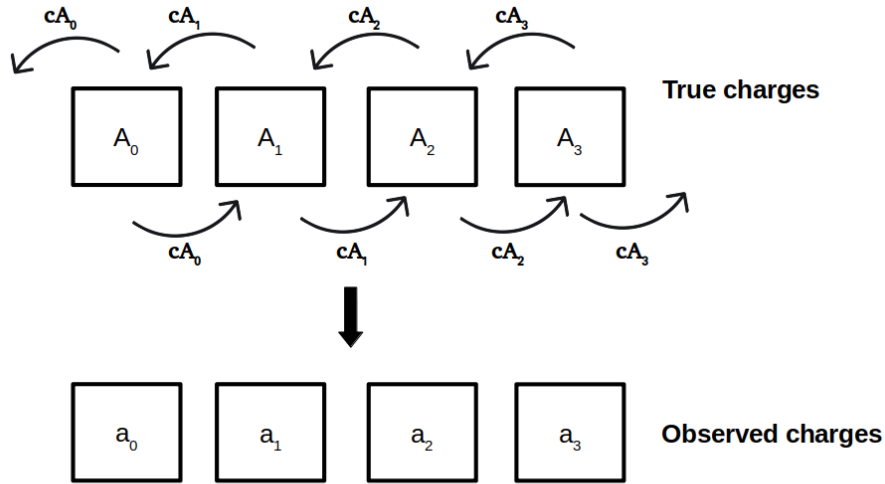

Figure 3.6: Relationship between the *real* strip charges  $A_i$  and the *observed* charges  $a_i$ , depending on the *unfolding coefficient*  $c$ . For the edge real charges (here  $A_0$  and  $A_3$ ), the outermost arrows represent lost charge.

922 To each *observed* cluster of size  $n$ , composed by the strips with charges  $a_i$ ,  
 923  $i \in (0; n - 1)$ , we want to associate the corresponding *true* cluster composed by the  
 924 strips with charges  $A_i$ . We define the Unfolding Matrix  $M$  of size  $n \times n$  such as:

$$\begin{cases} M_{ij} = 1 - 2c & \text{if } i = j; \\ M_{ij} = c & \text{if } |i - j| = 1; \\ M_{ij} = 0 & \text{for all others } (i, j); \end{cases} \quad (3.6)$$

925 With  $i, j \in (0, n - 1)$  and the *unfolding coefficient*  $c = 0.06$  (corresponding to the  
 926 expected 6% loss of charge for a given strip).

927 The *true* strip charges  $A_i$  are then computed as:

$$\begin{pmatrix} A_0 \\ A_1 \\ \dots \\ A_{n-1} \end{pmatrix} = M^{-1} \begin{pmatrix} a_0 \\ a_1 \\ \dots \\ a_{n-1} \end{pmatrix} \quad (3.7)$$

### 928 3.3.2 Implementation in the Belle II analysis software

929 In order to evaluate the effect of the unfolding method on the cluster position resolu-  
 930 tion, the method has been implemented in the Belle II analysis software. While strip  
 931 charges are used in the reconstruction process at different stages (*e.g.* evaluation of  
 932 the cluster time, see Equation 3.3), these processes give good results. Because the  
 933 development of the unfolding method is performance-motivated, we prefer not to

934 alter the computation methods giving satisfactory results. Thus, the scope of this  
 935 implementation is to correct strip charges with the unfolding method and to use  
 936 these corrected charges only in the computation of the cluster position.

937 The unfolding method is implemented by defining a new reconstruction function  
 938 which takes a reconstructed cluster as argument and returns a cluster with the  
 939 same attributes, except for the strip charges which are corrected as seen in [Equa-](#)  
 940 [tion 3.7](#). The unfolding coefficient  $c$  is defined with a different value for u/P and  
 941 v/N-side strips. The corrected strip charge is compared to a threshold  $T$  and set to  
 942 0 if its value is lower than  $T$  (so that the strip will not affect the CoG computation  
 943 of the cluster position).

944 A threshold is already defined in `basf2` to discard noisy strips: a given strip  $S_i$  with  
 945 strip noise  $N_i$  is discarded if its charge is below  $3 \times N_i$ , as seen in [Equation 3.1](#), with  
 946 the average noise being:

$$\left\{ \begin{array}{l} L_{3u} : 1100 \text{ ADC}; \\ L_{456u} : 900 \text{ ADC}; \\ L_{3v} : 900 \text{ ADC}; \\ L_{456v} : 600 \text{ ADC}; \end{array} \right. \quad (3.8)$$

947 Ideally the *unfolding* threshold  $T$  should also be defined strip by strip. Here,  
 948 two  $T$  values have been implemented:  $T = 0 \text{ ADC}$  in order to discard negative (non  
 949 physical) corrected strip charges, and  $T = 3000 \text{ ADC}$  as a general value correspond-  
 950 ing to  $\simeq 3 \times N_i$  for any given strip.

### 951 3.3.3 Datasets

952 Several datasets have been used in the developement of the unfolding method. Two  
 953 event topologies are studied:

- 954 • **di-muon samples:** these samples correspond to  $e^+e^- \rightarrow \mu^+\mu^-$  events. These  
 955 events are selected so that the two muon tracks have a transverse momentum  
 956  $p_T > 1.0 \text{ GeV}/c$ , come from a region close to the interaction point and are of  
 957 good quality with regards to the tracking (more than one hit in the PXD, 8  
 958 in the SVD and 30 in the CDC). Finally, only muon pairs with an invariant  
 959 mass between 10 and 11  $\text{GeV}/c^2$ .

960 These events consist solely of two clean and well-separated tracks, which allow  
 961 to gauge the performances of the detector in an optimal scenario.

- 963 • **hadronic events:** these samples are selected so that at least three tracks come  
 964 from the IP and verify  $p_T > 0.2 \text{ GeV}/c^2$  are kept. This loose selection allows  
 965 to discard several high cross-section processes (bhabha scattering, 4-electrons  
 966 production...) while retaining most hadronic events ( $e^+e^- \rightarrow B\bar{B}/q\bar{q}$ ).

967 These events allow to estimate the detector performances in the physics anal-  
 968 ysis regime, where the conditions are less than ideal because of varying track

969 quality, higher impact of multiple scattering due to a broader particle momen-  
970 tum distribution, etc..

971 Furthermore, the samples used in the estimation of the unfolding method perfor-  
972 mances are splitted between recorded data and simulation.

973 For Data:

974 • The preliminary tests and the optimization of the  $(c, T)$  values have been  
975 performed on  $\simeq 0.035 \text{ fb}^{-1}$  of data with both di-muon events and hadronic  
976 events. These have been selected amongst a sample of *good runs* for the SVD,  
977 corresponding to data taking periods for which the SVD data quality is known  
978 to be excellent.

979 Datasets using each possible  $(c, T)$  couples have been produced for both sample  
980 types.

981 • Final results have been extracted from  $\simeq 1 \text{ fb}^{-1}$  of data, using the same  
982 reconstruction on dimuon events.

983 For Simulation:

984 • Sets of 500k dimuon events (corresponding to  $\sim 0.043 \text{ fb}^{-1}$ ) have been gener-  
985 ated and reconstructed. Because the unfolding method is solely applied  
986 on recorded data, these samples have been used as a baseline to which the  
987 corrected datasets have been compared.

### 988 3.3.4 Effects on the position resolution

989 A full performance study has been performed, in order to assess the scale of the  
990 correction. The position resolution is first estimated for each  $(c, T)$  couple in di-  
991 muon events, as seen in [Figure 3.7](#) and [3.8](#). A threshold value of 3000 ADC slightly  
992 worsens the resolution for every values of  $c$  in most cases. The same study has been  
993 performed on hadronic events with the same effect being observed (*cf.* [Appendix A](#)).  
994 Taking  $T = 0$  thus seems a reasonable choice motivated both by detector perfor-  
995 mances and physical consideration. Indeed, further inspection validates that the  
996 majority of strip charges that would end up below 3000 ADC after the unfolding  
997 end up with negative (non-physical) charges and are cut away by a 0 ADC threshold.

998  
999 Furthermore, several sensor types are used in the SVD as described in [Table 2.2](#).  
1000 In order to assess if a sensor-dependent  $c$  value is needed, the impact of the unfolding  
1001 method on the spatial resolution has been studied for all sensor types for each  $c$   
1002 values ([Figure 3.9](#)). Finally, the effect of the correction has also been studied based  
1003 on the angle between the tracks considered and the sensors ([Appendix A](#)).

1004 The correction does not have a clear positive effect on V-side sensors. However, an  
1005 improvement is seen on U-side sensors, for which the optimal  $c$  value varies between  
1006 0.05 and 0.15 depending on the incident angle between the track and the sensor.  
1007 However, the ranking of performance gained from the different  $c$  values is not clear,

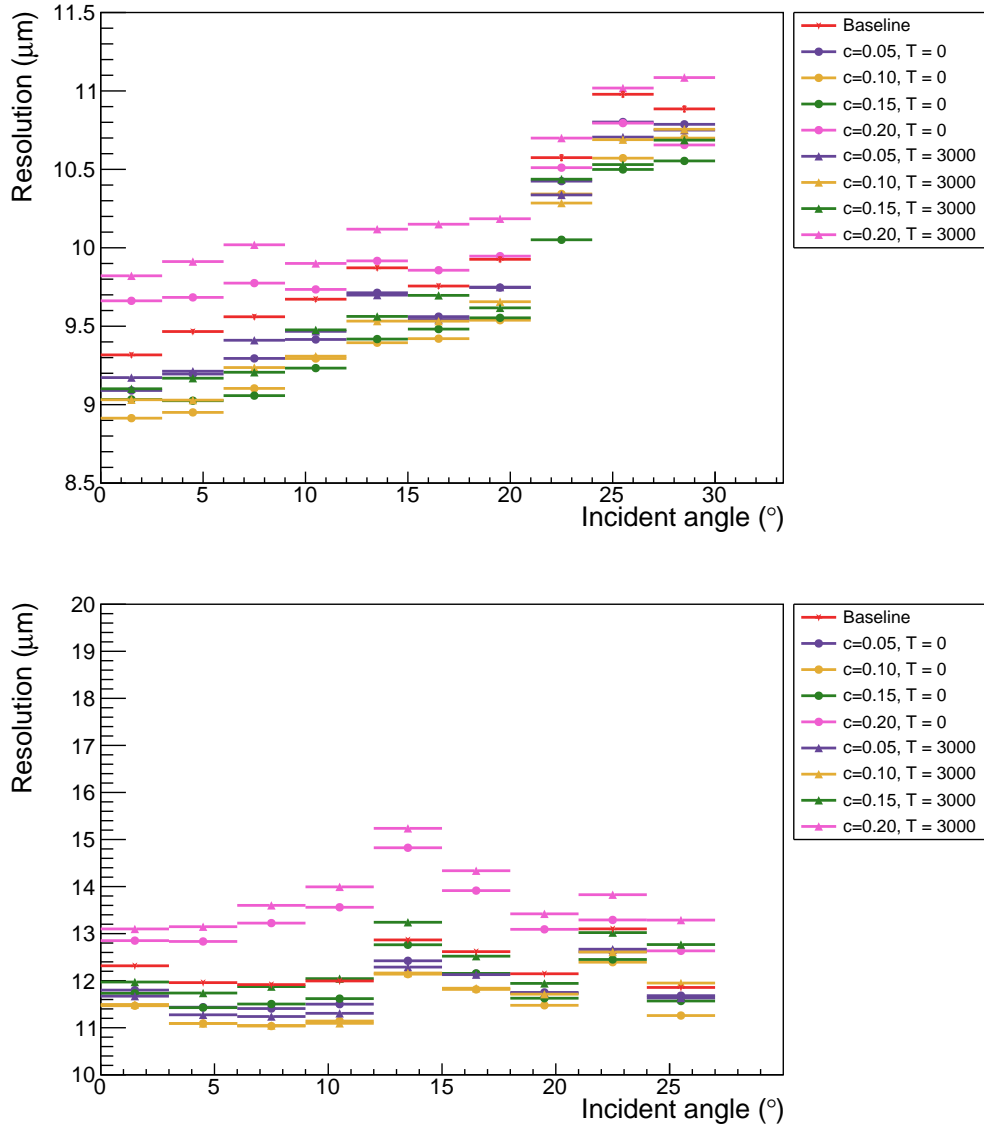

Figure 3.7: Cluster position resolution as a function of the incident angle of the track for all  $(c,T)$  couples. Each color corresponds to a given  $c$  value, circle markers correspond to  $T = 0$  ADC and triangle markers correspond to  $T = 3000$  ADC. The red points correspond to the baseline (*i.e.* no correction applied). For the Layer 3 u/P-side (top) and Layer 4,5 and 6 u/P-side (bottom).

Figure 3.8: Cluster position resolution as a function of the incident angle of the track for all  $(c, T)$  couples. Each color corresponds to a given  $c$  value, circle markers correspond to  $T = 0$  ADC and triangle markers correspond to  $T = 3000$  ADC. The red points correspond to the baseline (*i.e.* no correction applied). For the Layer 3 v/N-side (top) and Layer 4,5 and 6 v/N-side (bottom).

1008 due to statistical fluctuations. When taking the cluster position resolution for a  
1009 given sensor type averaged over all incident track angles (Table 3.1),  $c = 0.1$  always  
1010 leads to the best results.

1011 This value is close to the estimated effect ( $\simeq 6\%$  of the seed strip charge) of the  
1012 observed APV channels cross talk. The fact that the optimal value observed is  
1013 slightly higher than the expected one could be explained by other processes that  
1014 have yet to be identified but end up being (partially) corrected by the unfolding  
1015 method.

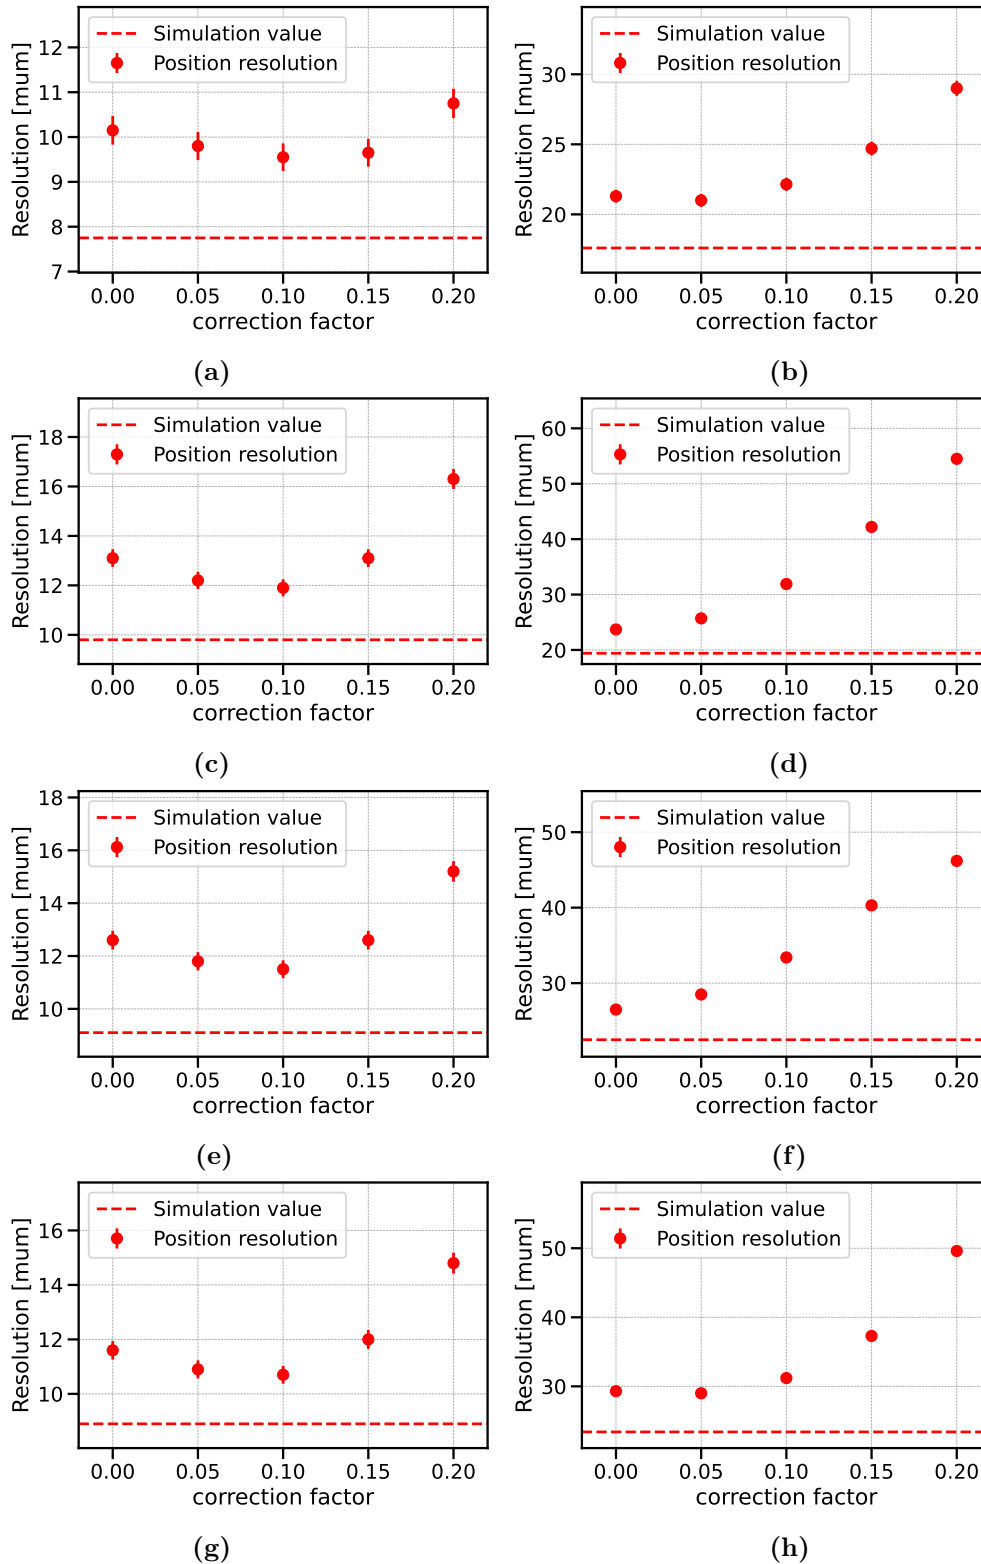

Figure 3.9: Averaged cluster position resolution depending on the value of the unfolding coefficient  $c$  for the Layer 3 u/P-side (a) and v/N-side (b) and Layer 4, 5 and 6 u/P-side backward sensors (e), v/N-side backward sensors (f), Layer 4, 5 and 6 u/P-side backward sensors (g), v/N-side backward sensors (h). The dashed red line corresponds to the position resolution computed in the simulation.

1016 **3.4 Conclusion**

1017 All things considered, applying the unfolding method on all the clusters with an  
 1018 unfolding coefficient of 0.1 and a threshold of 0 ADC allows to improve the overall  
 1019 cluster position resolution of u-side sensors by 5% to 15%, depending on the sensor  
 1020 type. Because this effect is not simulated, only collected data is corrected by the  
 1021 method, which subsequently reduces the disagreement on cluster position resolution  
 1022 seen between data and simulation (Figure 3.10).

Sensors - u-side	$c = 0$	$c = 0.05$	$c = 0.1$	$c = 0.15$	$c = 0.20$

1023

1024 The evolution with time and instantaneous luminosity conditions of the effect  
 1025 studied here and its correction is not yet known, thus this study will need to be  
 1026 conducted again in the future in order to ensure an optimal correction to the cluster  
 1027 position resolution.

1049 The different analysis techniques and tools used in this work are reported in this  
 1050 chapter. The next sections are rather independent as they treat of various subjects.  
 1051 [Section 4.1](#) provides a description of the algorithm used to perform  $B$ -meson tagging  
 1052 in the Belle II experiment while [Section 4.2](#) consists in a brief overview of binary  
 1053 classification. [Section 4.3](#) presents a figure of merit used in our search for the  
 1054  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay, adapted from the work of G. Punzi [100]. [Section 4.4](#) and [4.5](#)  
 1055 describe the statistical tools used to extract  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$  from observations, as  
 1056 well as the way experimental uncertainties are propagated to the final measurement.  
 1057 In the absence of clear signal observation, [Section 4.6](#) shows how an upper limit on  
 1058 the value of the branching fraction can be computed. Finally, [Section 4.7](#) introduces  
 1059 the concept of *blind* analyses and the reasons to proceed in such a manner.

1060 Because of the technicality and variety of subjects found in this chapter, the  
 1061 reader may skip it and come back to it when specific topics are referenced in [Chap-](#)  
 1062 [ter 5](#).

## 1063 4.1 The Full Event Interpretation algorithm

1064 This analysis makes use of the Belle II-developed Full Event Interpretation (FEI)  
 1065 algorithm [101]. The FEI is a hierarchical reconstruction algorithm estimating the

Figure 4.1: Schematic view of the  $\Upsilon(4S)$  decay showing (left) a generic *tag-side* and (right) the *signal-side*  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay. It is important to note that this separation is only conceptual and that the tracks coming from both sides overlap spatially in the detector. Adapted from [101].

1066 most probable decays of  $B$  mesons in  $\Upsilon(4S) \rightarrow B\bar{B}$  events based on detector infor-  
 1067 mation.

1068 This algorithm has been specifically developed to help the study of  $B$  meson decays  
 1069 with undetectable final state particles, such as  $B \rightarrow D^* \ell \nu$  and  $B^+ \rightarrow K^+ \nu \bar{\nu}$ . The  
 1070  $\Upsilon(4S)$  decay can be split into two conceptual sides. The *signal-side* corresponds  
 1071 to the tracks and calorimeter clusters compatible with the decay of interest. The  
 1072 *tag-side* contains the remaining objects in the event, compatible with any decay  
 1073 of the  $B$ -meson. The  $B$ -meson associated to each side are labeled  $B_{sig}$  and  $B_{tag}$   
 1074 respectively. Figure 4.1 illustrates this concept.

1075 First, tracks, displaced vertices (*i.e.* sets of tracks not originating from the interac-  
 1076 tion point) and calorimeter clusters of an event are identified. These objects are com-  
 1077 bined to reconstruct the final state particles of the event ( $e^\pm, \mu^\pm, \pi^\pm, K^\pm, p^\pm, n, \gamma$   
 1078 and  $K_L^0$ ). Afterwards, these final state particles are combined to form intermediate  
 1079 particles ( $\pi^0, D^{\pm/0}, J/\psi, K_S^0, D^{*\pm/0}$  and baryons). Latter stages of the reconstruc-  
 1080 tion allow to combine previously reconstructed particles to form heavier intermediate  
 1081 particles. The last stage of the reconstruction combines intermediate and final state  
 1082 particles into  $B$ -mesons.

1083 For each step of this procedure, the probability of the reconstructed particle (and its  
 1084 associated decay chain) is estimated using a multivariate classifier trained on simu-  
 1085 lated events using several features (vertex position, particle four-momentum, etc.).  
 1086 The output of said classifier is called  $\mathcal{P}_{FEI}$  and can be interpreted as a probability  
 1087 of correct identification. This reconstruction process is illustrated in Figure 4.2.

1088 The FEI is an *exclusive* tagging algorithm, meaning that it reconstructs parti-  
 1089 cles (in this case  $B_{tag}$ ) through explicit decay channels. Taking into account all  
 1090 intermediate particle decays implemented in the FEI, the algorithm can reconstruct  
 1091  $\mathcal{O}(10000)$  different decay chains. For our analysis, it provides  $B^+$  mesons in 36  
 1092 hadronic modes. The different modes are shown in Table 4.1.

1093 The FEI tag-side efficiency for fully hadronic  $B^+$  reconstruction is  $\simeq 0.66\%$ , includ-

Figure 4.2: Conceptual overview of the FEI algorithm reconstruction steps. The objects in gray boxes correspond to objects built by the Belle II reconstruction software. Taken from [101].

1094 ing branching fractions and reconstruction efficiency.

## 1095 4.2 Binary classification

1096 We discuss techniques used in this work to classify the events studied. Our goal is to  
 1097 separate **signal** (events where a  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay is present) from **background**  
 1098 (all other events). Several approaches can be adopted to do so, resulting in different  
 1099 efficiencies in the classification and purities.

1100 We present here two algorithms used to perform this task: the decision tree and  
 1101 the boosted decision tree. Similarly to a cut-based selection, these methods extract  
 1102 information from a set of discriminative variables to classify events in the defined  
 1103 classes. However, many events do not exhibit *all* characteristics of either classes.  
 1104 These methods allow to keep events rejected by a criterion and check if other criteria  
 1105 allow to classify them properly.

1106

### 1107 4.2.1 Decision tree

1108 Considering a set of  $N_v$  explanatory variables, a binary decision tree recursively  
 1109 splits the  $N_v$ -dimensional variable space based on binary selections. A first node  
 1110 divides the space into two subspaces based on a splitting value defined for a specific  
 1111 variable. The splitting value is chosen to maximize the separation (*i.e.* keeps mostly  
 1112 signal in one branch, mostly background in the other). This optimization is done

	$B^+$ decay modes

33	$B^+ \rightarrow \bar{D}^{0*} p \bar{p} \pi^+$
34	$B^+ \rightarrow D^+ p \bar{p} \pi^+ \pi^-$
35	$B^+ \rightarrow D^{+*} p \bar{p} \pi^+ \pi^-$
36	$B^+ \rightarrow \Lambda_c^- p \pi^+$

Table 4.1: List of the hadronic  $B^+$  meson decay modes reconstructed by the FEI algorithm and used in our analysis.

1113 by evaluating a loss function, here the cross-entropy:

$$\mathcal{L}(y, \hat{y}) = -[y \log \hat{y} + (1 - y) \log(1 - \hat{y})], \quad (4.1)$$

1114 Where  $y \in \{0, 1\}$  is the target class (background = 0, signal = 1) and  $\hat{y} \in (0, 1)$  is a  
 1115 prediction probability. This is repeated for following nodes, until reaching the final  
 1116 nodes, called leaves. Leaves correspond to a specific region of the variable space  
 1117 (defined by a succession of nodes, called branches) and are assigned weights. A  
 1118 negative weight corresponds to a background favoured prediction while a positive  
 1119 weight corresponds to a signal favoured prediction.

1120 To a given observation  $x \in \mathbb{R}^{N_v}$ , a decision tree  $m$  assigns a weight  $w(x) \in \mathbb{R}$ . The  
 1121 corresponding prediction probability  $\hat{y}(x)$  is then computed as:

$$\hat{y}(x) = P(w_m(x)) = \frac{1}{1 + e^{-w_m(x)}}, \quad (4.2)$$

1122 Decision trees prove to be useful tools to devise finer classifications (compared  
 1123 to cut-based techniques, of which they are a sequential generalization) and have  
 1124 the advantage of being easily interpreted as a set of boolean (here physics-based)  
 1125 decisions. However, they show high variance, as small changes in sample can greatly  
 1126 influence the output. Usually the classification power of a single decision tree can  
 1127 only marginally surpass that of random guesses.

### 1128 4.2.2 Gradient-boosted decision tree

1129 The issues linked to the use of a single decision tree can be addressed by employing  
 1130 *Boosted Decision Trees* (BDTs). BDTs are ensembles of decision trees, allowing  
 1131 to combine the output of the different trees to enhance the overall classification  
 1132 performances. For a given observation  $x \in \mathbb{R}^{N_v}$  and a set of  $N_t$  decision trees, a  
 1133 given tree assigns a weight  $w_i(x) \in \mathbb{R}$  to  $x$ . The weights of all trees in the ensemble  
 1134 can then be summed to define a global weight  $W(x)$ :

$$W(x) = \sum_{i=1}^{N_t} w_i(x), \quad (4.3)$$

1135 with an associated global prediction probability  $\hat{y}_g$  given by:

$$\hat{y}_g = P(W(x)), \quad (4.4)$$

1136 where  $P$  is defined in [Equation 4.2](#). To train a BDT, an initial weight  $w^0(x) = 0$   
 1137 is applied to all  $x$ . Each decision tree in the ensemble is then trained, iteratively  
 1138 solving:

$$w_m(x) = \arg \min_{w(x)} \left\{ \sum_{i=1}^{N_t} \mathcal{L}[y_i, P(w_{m-1}(x_i) + w(x))] + \Omega(w_m) \right\}, \quad (4.5)$$

1139 where  $w_{m-1}$  corresponds to the sum of the weights up to the previous iteration,  
 1140  $\mathcal{L}$  is the loss function defined in [Equation 4.1](#) and  $\Omega(w_m)$  is a regularization term

1141 penalizing complexity in the model, which helps prevent overfitting.  
1142 One way to solve Equation 4.5 is by computing the gradient of the loss function.  
1143 Thus, this variety of models are called gradient-boosted decision trees.  
1144 The analysis presented in Chapter 5 makes use of a gradient-boosted decision tree  
1145 algorithm, XGBoost [102].

### 1146 4.2.3 Variable importance

1147 Boosted decision trees are usually resistant to correlations amongst the explanatory  
1148 variables. They are also insensitive to variable duplicates and noise coming from  
1149 irrelevant variables. However, it is usually best to use as few features as possible, in  
1150 order to save computing time, mitigate the risk of variable simulation issues (since  
1151 it is trained on simulated data) and to facilitate the interpretation of the models.  
1152 In order to identify a reasonable set of input features, it is possible to rely on the  
1153 relative importance of the variables. To quantify this, we can define the gain pro-  
1154 vided by a tree node as the quantity by which the objective function (Equation 4.5)  
1155 is modified by said node. The importance of a given variable  $v$  can then be defined  
1156 as the sum of the gains across all nodes featuring  $v$ , normalised by the total gain:

$$I(v) = \frac{\sum_{i \in S^0} \text{Gain}(i)}{\sum_{j \in S} \text{Gain}(j)}, \quad (4.6)$$

1157 with  $I(v)$  the relative importance of  $v$ ,  $S^0$  the set of nodes featuring  $v$  and  $S$  the set  
1158 of all nodes present in the tree.

1159 Still, the relative importance of variables is difficult to assess. A potential short-  
1160 coming comes from *variable masking* [103]: considering two variables  $v_1$  and  $v_2$ , the  
1161 way  $I(v_2)$  is estimated in Equation 4.6 depends on the number of nodes featuring  
1162  $v_2$ . However, if  $v_2$  is only slightly less discriminative than  $v_1$ , it ends up featured  
1163 in fewer nodes and is then considered as irrelevant. However, removing  $v_1$  from the  
1164 features set renders  $v_2$  very relevant.

1165 A possible way to identify an optimal set of variables is to start with a set of  $n$   
1166 variables, train the model with all  $n - 1$  combinations and pick the combination  
1167 with the best performances and repeat it. This allows to identify which variables  
1168 have the largest effect on the classifier performance.

### 1169 4.2.4 k-folding

1170 K-folding is a form of cross-validation used to evaluate classifier's ability to adapt to  
1171 new data. In the case of particle physics analyses using classifiers, it can prove use-  
1172 ful to make the most out of a limited dataset. K-folding and other cross-validation  
1173 methods allow to gauge the overfitting of a classifier. Overfitting corresponds to the  
1174 dependence of the classifier on the data on which it is trained and is illustrated in  
1175 Figure 4.3.

1176 Considering a dataset  $\mathcal{L}$  on which to train a classifier, k-folding validation consists

Figure 4.3: Schematic view of the effects of overfitting. Suppose a classifier trained to separate two classes (red/blue dots), the black line corresponds to a generalized model, which would perform adequately on a different dataset. The green line corresponds to an overfitted model, which, even though giving a better separation power on the training data, is too reliant on that dataset and would likely show a worse separation power on a new dataset.

1177 in splitting said dataset in  $k$  equal sized subsamples  $\mathcal{L}_i$  such that  $\mathcal{L} = \bigcup_{i=1}^k \mathcal{L}_i$ . Of  
 1178 these subsamples,  $k - 1$  are used to train the model while the remaining one is used  
 1179 for testing. This is done  $k$  times, changing the training sample each time. In the  
 1180 end, the  $k$  training results can be averaged.

1181

### 1182 4.3 Modified Punzi figure of merit

1183 In [100], the computation of a figure of merit for optimizing a Poisson distributed  
 1184 event counting experiment is described. A *sensitivity region* is defined for a given  
 1185 confidence level CL:

$$1 - \beta_\alpha(\mu_{sens}) > CL, \quad (4.7)$$

1186 as the region of parameters for which the experiment is sensitive, with  $\alpha$  the signif-  
 1187 icance of the test and  $\beta$  the probability of rejecting the signal strength  $\mu_{sens}$  with  
 1188 the given confidence level. The definition of this sensitivity region means that the  
 1189 experiment is expected to lead to a discovery with a probability greater than CL  
 1190 with significance  $\alpha$  and can at least exclude the entire region in case the observed  
 1191 number is the maximum that does not allow to observe the signal with significance  
 1192  $\alpha$ .

1193 In the original case of a counting event, the sensitivity region can be defined by the  
 1194 number of signal events:

$$S_{sens} = a\sqrt{B} + b\sqrt{B + S_{sens}}. \quad (4.8)$$

1195 With  $B$  the number of background events and  $a$  and  $b$  the number of standard devi-  
 1196 ation corresponding to one-sided Gaussian tests at significance  $\alpha$  and  $\beta$  respectively.  
 1197 Solving for  $S_{sens}$  gives a figure of merit which one can minimize to find the best  
 1198 selection for a counting experiment.  
 1199 Here we propose a modified version of this figure of merit applicable to our anal-  
 1200 ysis. Considering the histograms  $B_i$  and  $S_i$  with the background and signal event  
 1201 distribution, we expect in each bin:

$$N_i = B_i + \mu' S_i. \quad (4.9)$$

1202 Where  $\mu'$  is the true value of the signal strength  $\mu$ . In each bin we can estimate  $\hat{\mu}_i =$   
 1203  $N_i - B_i/S_i$  with an uncertainty  $\sigma_{\hat{\mu}_i} = \sqrt{N_i}/S_i$  (Gaussian-Poisson approximation).  
 1204 By averaging the  $\hat{\mu}_i$  using as weights the inverse of their squared uncertainties, we  
 1205 get

$$\hat{\mu} = \mu', \quad \sigma_{\hat{\mu}} = \frac{1}{\sqrt{\sum \frac{1}{\sigma_{\hat{\mu}_i}^2}}} = \frac{1}{\sqrt{\sum \frac{S_i^2}{B_i + \mu' S_i}}}. \quad (4.10)$$

1206 This allows us to define the sensitivity region as:

$$\mu_{sens} = a\sigma_0 + b\sigma_{\mu_{sens}} \quad \text{with} \quad \sigma_0 = \frac{1}{\sqrt{\sum \frac{S_i^2}{B_i}}}, \quad \sigma_{sens} = \frac{1}{\sqrt{\sum \frac{S_i^2}{B_i + \mu_{sens} S_i}}}. \quad (4.11)$$

1207 It is then possible to numerically solve for  $\mu_{sens}$  and minimize it to optimize our  
 1208 selection.

## 1209 4.4 Binned maximum-likelihood fit

1210 We aim at measuring the value of  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$ , being motivated in part by the  
 1211 search for beyond Standard Model physics, as mentioned in [Section 1.4](#). We define  
 1212 the *signal strength*  $\mu$  as:

$$\mu = \frac{\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})}{\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})_{SM}}, \quad (4.12)$$

1213 which is the ratio of the measured branching fraction and the value predicted in the  
 1214 SM.

1215 As described in [Section 5.5](#), we base our measurement on the observed binned dis-  
 1216 tribution of a classifier of data events. In order to estimate  $\mu$ , we propose to perform  
 1217 a binned maximum-likelihood fit to this distribution. The method is discussed at  
 1218 length in [\[104, 105\]](#) and summarized below.

1219 For a set of  $N_b$  bins counting events after a given selection, the expected number of  
 1220 events  $\nu_1, \dots, \nu_{N_b}$  in each bin is estimated from simulation for each type of contri-  
 1221 butions from several event types, one signal sample and  $n \geq 1$  background sources:

1222

$$\nu_b(\mu, \boldsymbol{\theta}) = \sum_{t \in \{\text{event types}\}} \nu_{b,t}(\mu, \boldsymbol{\theta}), \quad (4.13)$$

1223 where  $\nu_{b,t}$  is the expected number of events in bin  $b$  for the event category sample  $t$   
 1224 and  $\boldsymbol{\theta}$  is a vector of  $N$  nuisance parameters which may impact the base expectations.  
 1225 Assuming  $n \geq 1$  background sources,  $\boldsymbol{\theta}$  contains  $n$  nuisance parameters  $\mu_1, \dots, \mu_n$ ,  
 1226 and  $N - n$  additional nuisance parameters such that:

$$\boldsymbol{\theta} = (\mu_1, \dots, \mu_n, \theta_{N-n}, \dots, \theta_N)^T, \quad (4.14)$$

1227 the normalisation parameters  $\mu_i, i \in \{1, \dots, n\}$  are voluntarily named similarly to  
 1228 the signal strength  $\mu$ , as each  $\mu_i$  corresponds to a given background strength. We  
 1229 can then develop [Equation 4.13](#) as:

$$\nu_b(\mu, \boldsymbol{\theta}) = \sum_{t \in \{\text{event types}\}} \mu_t (\nu_{b,t}^0, \Delta_{b,t}(\boldsymbol{\theta})), \quad (4.15)$$

1230 with  $\nu_{b,t}^0$  the nominal number of expected events in bin  $b$  for the event type  $t$  and  
 1231  $\mu_t$  is the normalisation parameter associated to the event type  $t$  (kept at the same  
 1232 value for all bins).  $\Delta_{b,t}(\boldsymbol{\theta})$  is an additive variation in the bin  $b$  for the sample  $t$  such  
 1233 as:

$$\Delta_{b,t}(\boldsymbol{\theta}) = \sum_{i=N-n+1}^N \theta_i \delta_{b,t}^i, \quad (4.16)$$

1234 where  $\delta_{b,t}^i$  is an additive variation for the bin  $b$  and the sample of event type  $t$ . This  
 1235 variation is modulated by the nuisance parameter  $\theta_i$ . The set of  $\delta_{b,t}^i$  is an input of  
 1236 the model, describing the systematic uncertainties. If for a given  $\theta_i$  one has  $\delta_{b,t}^i \neq 0$   
 1237 for multiples bins  $b$  or background samples  $t$ , then the  $\delta_{b,t}^i$  describe uncertainties  
 1238 correlated among the bins or the samples and are then interpreted as components  
 1239 of a variation vector of correlated uncertainties. The following cases arise:

- 1240 • Uncertainties are uncorrelated: one  $\theta_i$  is associated to each bin and sample,
- 1241 • Uncertainties are bin-correlated: one  $\theta_i$  is associated to each sample,
- 1242 • Uncertainties are sample-correlated: only one  $\theta_i$  is defined for all contributions.

1244 From these cases, we define the following uncertainty categories:

- 1245 • **Normalization:** the parameters cause a global scale variation on all bins.  
 1246 The effect is different and uncorrelated for the different components;
- 1247 • **Normalization-correlated:** the parameters induce a global scale variation  
 1248 on all bins, with correlation among components;
- 1249 • **Bin-correlated:** the parameters cause correlated bin-by-bin variations for  
 1250 each component, with no correlation among components;
- 1251 • **Component-correlated:** the parameters create correlated bin-by-bin varia-  
 1252 tion on each component, with correlation among components;

1253 • **Uncorrelated:** the parameters cause totally uncorrelated bin-by-bin varia-  
1254 tion on each component.

1255 Given the same set of  $N_b$  bins in which  $n_1, \dots, n_{N_b}$  data events are observed, we can  
1256 now model the likelihood of the observation as:

$$\mathcal{L}(\mu, \boldsymbol{\theta} | n_1, \dots, n_{N_b}) = \frac{1}{Z} \prod_{b \in \{\text{bins}\}} \text{Pois}(n_b | \nu_b(\mu, \boldsymbol{\theta})) p(\boldsymbol{\theta}), \quad (4.17)$$

1257 where  $Z$  is a simple normalization parameter (having no impact on the fit),  
1258  $\text{Pois}(n_b | \nu_b(\mu, \boldsymbol{\theta}))$  corresponds to the Poisson density function with expectation  
1259  $\nu_b(\mu, \boldsymbol{\theta})$  evaluated at  $n_b$  and  $p(\boldsymbol{\theta})$  is the prior probability given to the different  
1260 nuisance parameters.

1261 Said prior probability contains information on how the systematic uncertainties are  
1262 modelled. It is the product of several Gaussian densities centered at unity for the  
1263 normalisation variations and at zero for the additive variations:

$$p(\boldsymbol{\theta}) = \prod_{i=1}^n \text{Gauss}(\theta_i | 1, \sigma_{norm,i}^2) \prod_{j=N-n+1}^N \text{Gauss}(\theta_j | 0, 1), \quad (4.18)$$

1264 where  $\text{Gauss}(x | m, \sigma^2)$  is the Gaussian density with expectation  $m$  and variance  $\sigma^2$ .  
1265 The background normalization uncertainties  $\sigma_{norm,i}$  are inputs of the model, simi-  
1266 larly to the  $\delta_{b,t}^i$  factors seen in Equation 4.16. We see that the parameter of interest  
1267  $\mu$  is not present in Equation 4.18. This is because  $\mu$  is unconstrained, meaning that  
1268 its prior distribution is uniform.

1269 The parameter of interest  $\mu$  is finally extracted from data by maximizing the likeli-  
1270 hood function defined in Equation 4.17. In our analysis, a software package called  
1271 pure-python HistFactory (pyhf [105]) is used to implement this method as well as  
1272 the statistical model.

## 1273 4.5 Propagation of uncertainties

1274 As with any measurement, the value of  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$  measured here is expected  
1275 to be given with associated uncertainties. Several systematic uncertainty contri-  
1276 butions in our analysis come from pre-existing measurements (*e.g* branching ratio  
1277 values of  $B$  mesons decays used for the simulation) whose uncertainties need to be  
1278 propagated to the statistical model described in Section 4.4. We describe here a gen-  
1279 eral method to do so, varying input values based on their respective uncertainties  
1280 and transforming this information to feed it to our statistical model.

1281

### 1282 4.5.1 Toy simulation

1283 Toy simulations are used to estimate the propagation of uncertainties on an event-  
1284 by-event basis. It consists of building a set of replicas created for each event con-  
1285 sidered. For each replica, a weight associated to the considered uncertainty source

1286 is computed. Considering a quantity of interest  $\theta$  with an associated uncertainty  
 1287  $\sigma$ , we create for each event  $e$  a set of  $N$  replicas. To each replica  $r \in \{1, \dots, N\}$  we  
 1288 associate a modified value  $\theta_r$  and a weight  $w_r^e(\theta)$  such that:

$$\theta_r^e = \theta^e + \mathcal{N}(0, \sigma), \quad (4.19)$$

1289

$$w_r^e = \frac{\theta_r^e}{\theta^e}. \quad (4.20)$$

1290 Here, we make the hypothesis that the uncertainty follows a gaussian distribution  
 1291  $\mathcal{N}(0, \sigma)$ .

1292 The bins of the statistical model are then filled appropriately with the replica, based  
 1293 on the bin value and category associated with the event  $e$ . Sums of weights  $S_i^r$   
 1294 are computed for the different replica, with  $i$  corresponding to the fit contribution  
 1295 category.

#### 1296 4.5.2 Estimation of the covariance matrix

1297 Using the sums of weights  $S_i^r$ , we can define a covariance matrix as:

$$C_{ij} = \sum_r \frac{(S_i^r - \bar{S}_i) (S_j^r - \bar{S}_j)}{N_r}, \quad (4.21)$$

1298 with the corresponding correlations:

$$\rho_{ij} = \frac{C_{ij}}{C_{ii} \cdot C_{jj}}, \quad (4.22)$$

1299 where  $\bar{S}_i$  is the average over all replicas of the sums of weights for a given bin  $i$ .  
 1300 The covariance matrix is an  $m \times m$  matrix, with  $m = n_{bins} \times n_{cat}$ .  $n_{bins}$  being the  
 1301 number of bins and  $n_{cat}$  the number of contribution categories used in the statistical  
 1302 model.

1303 The `pyhf` software package used for the implementation of the statistical model  
 1304 described in [Section 4.4](#) requires systematic uncertainties to be described as nuisance  
 1305 parameters. A possible approach is to use singular value decomposition (SVD). This  
 1306 allows to identify the most significant eigenvectors of the covariance matrix and  
 1307 add the remaining ones in quadrature, allowing to simplify the treatment of minor  
 1308 uncertainty sources.

1309 Because the covariance matrix  $\mathbf{C}$  is real, symmetric and positive semi-definite, there  
 1310 exists  $m$  orthogonal unit eigenvectors  $\hat{\mathbf{u}}_1, \dots, \hat{\mathbf{u}}_m$  with associated eigenvalues  
 1311  $\lambda_1 \geq \dots \geq \lambda_m \geq 0$  such that:

$$\mathbf{C} = \mathbf{Q}\mathbf{\Sigma}\mathbf{Q}^T = \sum_{i=1}^m \lambda_i \hat{\mathbf{u}}_i \hat{\mathbf{u}}_i^T, \quad (4.23)$$

1312 where  $\mathbf{Q}$  is the  $m \times m$  matrix whose columns are the eigenvectors and  $\mathbf{\Sigma}$  is the diag-  
 1313 onal matrix whose non-zero elements are the corresponding eigenvalues. Ordering

1314 said eigenvalues, if the first  $t < m$  eigenvalues are significantly larger than the rest,  
 1315 we can assume:

$$\mathbf{C} \approx \sum_{i=1}^t \lambda_i \hat{\mathbf{u}}_i \hat{\mathbf{u}}_i^T + \text{diag} \left( \sum_{j=t+1}^m \lambda_j \hat{\mathbf{u}}_j \hat{\mathbf{u}}_j^T \right), \quad (4.24)$$

1316 so that only the diagonal elements of the  $p$  through  $t$  minor terms are considered.  
 1317 Nuisance vectors  $\lambda_i = \lambda_i \hat{\mathbf{u}}_i$  for  $i \in (1, t)$  can then be used to propagate correlated  
 1318 uncertainties to the statistical model while the remaining terms in Equation 4.24  
 1319 are treated as uncorrelated uncertainties.

## 1320 4.6 Upper limit determination

1321 Previous searches for the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay have seen no significant signal (see  
 1322 Section 1.5). Thus, we propose to determine an upper limit on the signal strength  
 1323  $\mu$  defined in Equation 4.12.

1324 From the likelihood model defined in Equation 4.17 and an assumed  $\mu$  value, we can  
 1325 define the likelihood ratio:

$$\lambda(\mu) = \frac{\mathcal{L}(\mu, \hat{\boldsymbol{\theta}} | n_1, \dots, n_{N_b})}{\mathcal{L}(\hat{\mu}, \hat{\boldsymbol{\theta}} | n_1, \dots, n_{N_b})}, \quad (4.25)$$

1326 where the parameters  $(\hat{\mu}, \hat{\boldsymbol{\theta}})$  maximize the likelihood for the set of observations  
 1327  $\{n_1, \dots, n_{N_b}\}$  when the value  $\hat{\mu}$  is allowed to fluctuate. In addition,  $\hat{\boldsymbol{\theta}}$  maximizes the  
 1328 likelihood for the same set of observations and a fixed  $\mu$  value [106].

1329 We can then define a likelihood-ratio test  $A_\mu$ :

$$A_\mu = -2 \ln \lambda(\mu), \quad (4.26)$$

1330 the  $-2$  factor ensures that  $A_\mu$  approaches asymptotically the  $\chi^2$  distribution [107].  
 1331 It is then possible to evaluate an upper limit on  $\mu$  for a given confidence level (CL)  
 1332 by finding the value  $\mu$  verifying:

$$A_\mu = CDF_{\chi^2}^{-1}(\mathcal{C}), \quad (4.27)$$

1333 where  $\mathcal{C}$  corresponds to the required CL (ex: 0.9 for a 90% CL) and  $CDF_{\chi^2}^{-1}$  is the  
 1334 cumulative distribution function of the  $\chi^2$  distribution.

1335 The `pyhf` package is used for the upper limit determination.

## 1336 4.7 Blind analysis

1337 The analysis described in Chapter 5 is performed as a *blind analysis*. This allows  
 1338 to protect the analysis' result from potential biases. Some biases coming from the  
 1339 experimental apparatus have an effect on the result that can be gauged and are

1340 usually treated with systematic uncertainties associated to the result. Other biases,  
1341 coming from the person performing the measurement, are impossible to precisely  
1342 estimate. Blind analyses are performed to limit the effect of the latter.

1343 In this work, the analysis is developed using simulated physics samples. Which al-  
1344 lows to gauge the behavior of the different analysis parts, such as the reconstruction,  
1345 event classification and expected result. However, doing so exposes the analysis to  
1346 mis-modeling in the simulation. Thus, the analysis process is then cross-checked  
1347 using measured data, using specific selection criteria to identify independant data  
1348 samples containing as few signal as possible (*cf.* [Subsection 5.6.2](#) and [5.6.3](#)). Po-  
1349 tential discrepancies between data and simulation can, for example, be included in  
1350 the result as associated systematic uncertainties.

1351 Finally, once the sanity of the analysis has been duly checked, the analysis procedure  
1352 is applied on the full data sample (*unblinding*).

1390 After describing the main tools and methods used in the different stages of this  
 1391 analysis in the previous chapter, we now aim at describing the steps devised to  
 1392 measure the branching ratio  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$  using data collected by the Belle II  
 1393 experiment. This chapter first presents the overall selection method:

- 1394 • Data samples used in this analysis are described in [Section 5.1](#)
- 1395 • Event pre-selection ([Section 5.2](#)): Low-level objects are defined, before a broad  
 1396 selection is performed when reconstructing  $B_{tag}$  candidates using the FEI al-  
 1397 gorithm (described in [Section 4.1](#)). A tighter selection is then applied to create  
 1398 manageable datasets, based on the physical properties of the signal studied.
- 1399 • Signal candidate selection ([Section 5.3](#)): In each event, one signal  $K^+$  is iden-  
 1400 tified and associated to a  $B_{tag}$  candidate.
- 1401 • Event classification ([Section 5.4](#)): A set of variables is defined to differentiate  
 1402 between signal events and events from background processes. These variables  
 1403 are then studied on simulated events. Afterwards, a multivariate classifier  
 1404 is built and trained on simulated samples to classify events based on their  
 1405 signal-likeness.

1406 The method is then validated using data, as a way to identify potential detector  
 1407 issues or mismodelling in the simulation ([Section 5.6](#)):

- 1408 • Validation using embedded signal ([Subsection 5.6.1](#)): Using  $B^+ \rightarrow K^+ J/\Psi(\mu^+ \mu^-)$   
 1409 events identified in data, we swap the  $K^+$  and  $J/\Psi(\mu^+ \mu^-)$  in the event with  
 1410 simulated  $K + \nu \bar{\nu}$  and match the kinematics to mimic our signal. We use this  
 1411 sample to control the behavior of signal events during the selection process.
- 1412 • Validation using off-resonance data ([Subsection 5.6.2](#)): Using data collected  
 1413 at an energy in the centre of mass frame 60 MeV below the mass of the  $\Upsilon(4S)$   
 1414 resonance, we control the behavior of  $e^+ e^- \rightarrow q \bar{q}$  events where  $q \in (u, d, s, c)$ .
- 1415 • Validation using on-resonance data ([Subsection 5.6.3](#)): We further validate  
 1416 the selection by defining two orthogonal samples in the signal region of data,  
 1417 with the requirements that these samples be dominated by background and  
 1418 only marginally populated by actual signal. This allows to study signal-like  
 1419 data events without introducing a bias by fine tuning parts of the analysis on  
 1420 data signal events.

1421 Finally, we develop a statistical model (described in [Section 4.4](#)) to measure the  
 1422 value  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$  (if not enough signal events are selected, we set an upper limit  
 1423 on this value). We also describe in [Section 5.7](#) the different sources of systematic  
 1424 uncertainty on our measurement, as well as the methods used to evaluate them.  
 1425 The final result of our measurement is presented in [Section 5.8](#).

## 1426 5.1 Input datasets

1427 The Belle II experiment aims at collecting  $50 \text{ ab}^{-1}$  of data at a collision energy  
 1428 corresponding to the mass of the  $\Upsilon(4S)$  resonance. The analysis described thereafter  
 1429 makes use of a data sample corresponding to  $362 \text{ fb}^{-1}$  collected at the energy of the  
 1430  $\Upsilon(4S)$  resonance between 2019 and the summer of 2022 when the first Belle II long  
 1431 shutdown was started, which corresponds to  $387.1 \times 10^6 B\bar{B}$  pairs. This sample is  
 1432 referred to as the *on-resonance data*.

1433 In addition, a sample of  $42 \text{ fb}^{-1}$  is collected at an energy 60 MeV below the  $\Upsilon(4S)$   
 1434 resonance and is used for validation. The interest in this sample comes from the  
 1435 fact that it does not contain any  $B$  meson decays, as its associated energy is not  
 1436 sufficient to produce them. We refer to this sample as *off-resonance data*.

1437 Finally, the following samples, simulated using the tools described in [Section 2.6](#) are  
 1438 used to develop the analysis:

- 1439 •  $50 \times 10^6 B^+ \rightarrow K^+ \nu \bar{\nu}$  events, referred to as *signal sample*,
- 1440 • A sample corresponding to  $1 \text{ ab}^{-1}$  of equivalent integrated luminosity of  
 1441  $e^+e^- \rightarrow q\bar{q}$  events, with  $q \in \{u, d, s, c\}$ , referred to as *continuum background*,
- 1442 • A sample corresponding to  $3 \text{ ab}^{-1}$  of equivalent integrated luminosity of  
 1443  $e^+e^- \rightarrow B\bar{B}$  events, referred to as  *$B\bar{B}$  background*,

1444 The simulated samples are taken from the official Belle II simulation production,  
 1445 produced with the tools described in [Section 2.6](#).

## 1446 5.2 Object selection

1447 The first step of the reconstruction in this analysis is the identification of  $B_{tag}$   
 1448 candidates using the FEI algorithm. This allows to fully reconstruct one of the  
 1449 two  $B$  mesons coming from the decay of the  $\Upsilon(4S)$  in the hadronic modes listed in  
 1450 [Table 4.1](#). Several  $B_{tag}$  candidates might be reconstructed for each event, with an  
 1451 associated probability  $\mathcal{P}_{FEI}$ . We then search for the signal signature ( $B_{sig} \rightarrow K^+ \nu \bar{\nu}$ )  
 1452 in their recoil, reconstructed with remnant tracks.

1453 To save computing time, reconstructed events are required to have at least 3  
 1454 tracks (see [\[97\]](#)), complying with the following requirements in order to be able to  
 1455 reconstruct a  $B_{tag}$ :

- 1456 • The transverse impact parameter of the track,  $|d_0|$  is lower than 0.5 cm and  
 1457  $|z_0|$ , its the longitudinal impact parameter, is lower than 2 cm (cf. [Figure 2.4](#)  
 1458 for a description of Belle II's coordinate system). This allows to discard events  
 1459 without enough charged particles originating from the interaction point.
- 1460 • The transverse momentum of the track,  $p_T$  must be greater than 0.1 GeV. This  
 1461 allows to discard a large portion of beam background tracks.

Charged particle	Fraction (%)
$\pi^\pm$	72.8
$K^\pm$	14.9
$e^\pm$	5.8
$\mu^\pm$	4.7
$p^\pm$	1.8

Table 5.1: Expected fractions of charged particles in  $B$ -meson decays. These are estimated from  $e^+e^- \rightarrow B\bar{B}$  events [108].

1462 These tracks are used to build charged particle candidates, identified amongst pi-  
 1463 ons, kaons, electrons, muons or protons using PID information from the different  
 1464 Belle II subdetectors (cf. Subsection 2.7.2 and 2.7.3). An additional identification  
 1465 probability is derived from simulated  $e^+e^- \rightarrow B\bar{B}$  events (Table 5.1).

1466

1467 Furthermore, considered events are required to contain at least 3 calorimeter  
 1468 clusters such that:

- 1469 • The cluster energy  $E$  is greater than 0.1 GeV/ $c$ , this allows to suppress a large  
 1470 portion of beam background.
- 1471 • The cluster polar angle  $\theta$  verifies  $0.297 < \theta < 2.618$  rad. This angular region  
 1472 corresponds to the CDC acceptance and so this requirement suppresses clusters  
 1473 potentially produced by charged particles that have not been tracked.

1474 These ECL (see Subsection 2.3.5) clusters are used to build photon candidates.

1475 Finally, we require that the total visible energy in the event be greater than 4 GeV  
 1476 and that the total energy deposited in the calorimeter be in the range [2, 7] GeV.  
 1477 The last two quantities are computed considering the tracks and clusters previously  
 1478 defined.

1479 Only  $B_{tag}$  candidates with a beam-constrained mass  $M_{bc}^* > 5.27 \text{ GeV}/c^2$  and  
 1480  $|\Delta E| < 0.3 \text{ GeV}/c$  are retained, with:

$$M_{bc}^* = \sqrt{\left(\frac{\sqrt{s}}{2c^2}\right)^2 - \left(\frac{p_B^*}{c}\right)^2}, \quad (5.1)$$

1481

$$\Delta E = \sqrt{E_B - \frac{\sqrt{s}}{2}} \quad (5.2)$$

1482 Where  $\sqrt{s}$  is the collision energy and  $p_B^*$  is the momentum of the  $B_{tag}$  candidate  
 1483 computed in the CMS, while  $E_B$  is the energy of the considered  $B$ -meson.

1484 To each  $B_{tag}$ , we assign a signal probability ( $\mathcal{P}_{FEI}$ ).  $\mathcal{P}_{FEI}$  is the output of the  
 1485 final FEI multivariate classifier that ranges from 0 (misreconstructed) to 1 (correctly  
 1486 reconstructed). For each  $B_{tag}$  candidate,  $\mathcal{P}_{FEI}$  is required to be greater than 0.001.  
 1487 Finally, events with more than 12 tracks with  $|z_0| < 4$  cm,  $|d_0| < 2$  cm are further  
 1488 rejected. With This requirement is due to the low multiplicity expected in signal  
 1489 events of the type  $\Upsilon(4S) \rightarrow B_{tag} + B_{sig}$ , with  $B_{tag} \rightarrow$  hadronic modes,  $B_{sig} \rightarrow K^+ \nu \bar{\nu}$ .

### 1490 5.3 Signal candidate selection

1491 As described in the previous section, several  $B_{tag}$  candidates might be reconstructed  
 1492 in each event. We then search a  $B_{sig}$  for each of them. Because  $B_{sig}$  decays as  
 1493  $B_{sig} \rightarrow K^+ \nu \bar{\nu}$  this comes down to pair each  $B_{tag}$  candidate to a  $K^+$  candidate.  
 1494 Down the line, only one set of  $B_{tag} + B_{sig}$  is retained.

1495 Signal kaon candidates are selected from tracks verifying:

- 1496 • Basic IP constraint:  $d_0 < 0.5$  cm,  $|z_0| < 2$  cm,
- 1497 • CDC acceptance requirement:  $0.297 < \theta < 2.618$ ,
- 1498 • Tracking quality: at least 20 hits in the CDC and 1 hit in the PXD,
- 1499 • Particle identification:  $kaonID > 0.9$ .

1500 This retains around 60% of true kaons and rejects around 95% of mis-identified  
 1501 kaons.

1502 Once a  $B_{tag}$  and signal side kaon have been paired together, the number of extra-  
 1503 tracks not associated to either  $B_{tag}$  nor to the  $K^+$  candidate is required to be zero.  
 1504 Such counting is done on objects with  $d_0 < 2$  cm,  $|z_0| < 4$  cm, reconstructed in CDC  
 1505 acceptance and with at least 20 CDC hits. In addition, we require that no additional  
 1506 reconstructed  $\pi^0$ ,  $K_S^0$  and  $\Lambda^0$  be left in the event. Afterwards, we define the rest-  
 1507 of-event (ROE), which consists of remaining tracks and ECl clusters not associated  
 1508 with either  $B_{tag}$  nor with  $B_{sig}$ . For perfectly reconstructed signal events, the ROE  
 1509 contains no particles. For mis-reconstructed events, given the aforementioned cut  
 1510 on extra-tracks, the ROE is formed by neutral deposits not associated with charged  
 1511 particles.

1512 In addition, we require that the  $B_{tag}$  and  $B_{sig}$  be of opposite electric charge. Finally,  
 1513 we compute the missing momentum vector  $\mathbf{p}_{miss}$  as:

$$\mathbf{p}_{miss} = - \sum_{i=1}^N \mathbf{p}_i \quad (5.3)$$

1514 Where  $N$  is the number of particle candidates in the event. The polar angle of  
 1515 the missing momentum,  $\theta_{miss}$  is required to verify  $0.3 < \theta_{miss} < 2.8$  rad, in order to  
 1516 make sure that the missing momentum is not due to particles escaping the detector  
 1517 acceptance.

1518 In order to retain a single  $B_{tag} + B_{sig}$  pair per collision, the  $B_{tag}$  candidate with  
 1519 the highest FEI probability is identified. This is done after the classifier selection  
 1520 (see [Section 5.5](#)).

## 1521 5.4 Background suppression

1522 The main challenge in observing the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  signal is the large background  
1523 contamination. Therefore, powerful background suppression is needed. After the  
1524 selection described in the previous section, we identify a set of discriminating vari-  
1525 ables used to train a multivariate classifier to separate signal and background. To  
1526 achieve optimal separation, we explore several categories of variables to extract dis-  
1527 tinctive signal feature information. The variables used are sensitive to the event  
1528 topology and kinematic properties of the ROE and  $B_{tag}$ , or characterize the signal  
1529 candidate. In addition, we consider variables obtained by reconstructing vertices  
1530 and invariant masses of two and three charged particles including the signal  $K^+$   
1531 candidate to identify and veto potential contributions from  $D^0$  and  $D^+$  meson de-  
1532 cays. Numerous variables are considered, though only a minimal set of variables  
1533 that are well described in the simulation are kept. The data-simulation agreement  
1534 is confirmed with control-sample studies, as described in [Section 5.6](#).

### 1535 5.4.1 Variables of interest

1536 A set of variables is built with the intent of using said variables as features for the  
1537 training of a multivariate classifier tasked with estimating the signal-likeness of the  
1538 event studied. The choice of variables is motivated by:

- 1539 • Number of features: In order to avoid correlations between variables and over-  
1540 complication of the classifier (see [Section 4.2](#)), we choose to select as few  
1541 features as possible, discarding variables showing a discriminative power under  
1542 a certain threshold.
- 1543 • Discriminative power: Features kept in the classification process should show  
1544 adequate discrimination between signal and background events. This is eval-  
1545 uated on the simulated samples described in [Section 5.1](#). The estimation of  
1546 this discriminative power is described in [Subsection 5.4.4](#).
- 1547 • Adequate modeling: The computation and testing of the variables of inter-  
1548 est being performed on simulated samples, it is important to check that they  
1549 are well modelled. Indeed, physical processes not taken into account during  
1550 simulation, or inefficiencies of the detectors can bias the distribution of the  
1551 computed features, compared with what is seen in recorded data. To avoid  
1552 these issues, the data/simulation agreement for the features is studied in sev-  
1553 eral control channels (see [Section 5.6](#)).

1554 The variables are split into different categories described as below. The distributions  
1555 shown in the different figures are based on the simulated samples mentionned in  
1556 [Section 5.1](#), after the selection steps described in [Section 5.3](#). The variables are  
1557 computed in the laboratory reference frame unless otherwise specified (some are  
1558 computed in the centre of mass frame, noted CMS). Distributions are normalized  
1559 to unitarity area.

### 1560 5.4.1.1 General event properties

1561 Several variables used in the classification are related to the geometrical distribution  
 1562 of reconstructed particles in the event or their multiplicity. These features are mainly  
 1563 computed using the momenta of the particles in the event.

1564 The event shape variables retained in the classification are:

- 1565 • The modified Fox-Wolfram moments  $H_{22}^{so}, H_{02}^{so}$  and  $H_0^{oo}$ , as described below,  
 1566 are computed in the CMS and provide good discrimination between signal and  
 1567  $q\bar{q}$  events. This is due to the difference in event shapes expected between the  
 1568 different event types.
  
- 1569 • The number of remaining tracks in the event. As mentioned in [Section 5.3](#), we  
 1570 require that no *clean* tracks remain in the event after reconstructing a  $\Upsilon(4S)$   
 1571 from a  $B_{tag}$  and  $B_{sig}$  pair. The feature computed here then corresponds to  
 1572 the number of tracks left in the event that do not meet the requirements to be  
 1573 classified as *clean* tracks. This variable proves to be extremely discriminative  
 1574 as signal events are expected to show exactly zero extra track, while the missing  
 1575 component of the signal can be mimicked in background events by low quality  
 1576 tracks not used in the reconstruction of the  $B_{tag}$  candidates.
  
- 1577 • The extra energy in the event associated to ECL clusters from neutral particles,  
 1578  $NE_{ECL}^{Extra}$ . This feature is defined as the sum of the energy from calorimeter  
 1579 clusters that are not associated to any track in the event. This extra energy in  
 1580 the event proves to be the most discriminative feature and is further detailed  
 1581 below.

1582 The distributions of these variables for simulated signal and background samples  
 1583 can be found in [Figure 5.1](#).

### 1584 Modified Fox-Wolfram moments

1585 Fox-Wolfram moments were first introduced by G. C. Fox and S. Wolfram to pro-  
 1586 vide variables to describe event shapes in  $e^+e^-$  annihilation [[109](#), [110](#)]. Modified  
 1587 Fox-Wolfram moments were later developed by the Belle collaboration [[69](#)].

1588 These variables are developed specifically within the framework of  $B$ -factories, di-  
 1589 viding particles produced in events into two conceptual classes:  $B$ -meson candidate  
 1590 daughters (labeled  $s$ ) and particles coming from the rest of the event (ROE), de-  
 1591 noted as  $o$ . For a given event, the total number of particles  $N$  verifies  $N = N_s + N_o$ ,  
 1592 with  $N_s$  and  $N_o$  corresponding to the number of particles in the  $s$  and  $o$  classes  
 1593 respectively. In addition, particles are further classified in 3 subsets labeled with  
 1594 integers: charged particles (label 0), neutral particles (label 1) and missing particles  
 1595 (label 2). It is worth noting that the entirety of the missing momentum in the event  
 1596 (defined in [subsection 5.4.1.4](#)) is treated as one missing particle.

1597 The signal-ROE ( $so$ ) modified Fox-Wolfram moment of degree  $l \in \mathbb{N}$  for the particle

1598 category  $x \in \{0, 1, 2\}$  is defined as:

$$H_{xl}^{so} = \frac{1}{Z} \sum_{i=1}^{N_s} \sum_{j_x=1}^{N_x} C_{ij_x}^l p_{j_x} P_l(\cos \alpha_{ij_x}), \quad (5.4)$$

1599 with:

- 1600 •  $Z$  a normalization factor verifying  $Z = 2(\sqrt{s} - E_B^*)$ , with  $\sqrt{s}$  the available
- 1601 energy in the center-of-mass frame and  $E_B^*$  the signal  $B$ -meson candidate
- 1602 energy in the center-of-mass frame.
- 1603 •  $C_{ij_x}^l \in \{-1, 0, 1\}$  the product of the charges for the candidates  $i$  and  $j_x$  if  $l$  is
- 1604 odd;  $C_{ij_x}^l = 1$  if  $l$  is even.
- 1605 •  $P_l$  the Legendre polynomial of  $l$ -th order.
- 1606 •  $\alpha_{ij_x}$  the angle between the momenta  $\mathbf{p}_i$  and  $\mathbf{p}_{j_x}$ .

1607 The ROE-ROE (oo) modified Fox-Wolfram moment of degree  $l$  can then be described

1608 as:

$$H_l^{oo} = \frac{1}{Z^2} \sum_{i=1}^{N_o} \sum_{j=1}^{N_o} C_{ij}^l p_i p_j P_l(\cos \alpha_{ij}), \quad (5.5)$$

1609 with the same notations as in [Equation 5.4](#).

### 1610 Extra energy in the calorimeter

1611 The extra energy from neutral sources in the event,  $NE_{ECL}^{Extra}$ , is computed from

1612 energy deposits in the ECL subdetector associated to photons in the *ROE* defined

1613 in [Section 5.3](#). These photon candidates must verify the following requirements:

- 1614 • The photon candidate associated cluster energy must be greater than (0.100,
- 1615 0.060, 0.150) GeV, for clusters in the (forward, barrel, backward) regions of
- 1616 the ECL.
- 1617 • The distance between the photon candidate and the closest track in the event
- 1618 must be greater than 50 cm.
- 1619 • The photon candidate must be within the CDC acceptance.

1620  $NE_{ECL}^{Extra}$  corresponds to the sum of the energy deposited in the ECL for each retained

1621 photon candidate.

#### 1622 5.4.1.2 B meson kinematic variables

1623 The kinematics of the signal kaon candidate are expected to vary between signal and

1624 background events. The relationship between the  $B_{tag}$  and  $B_{sig}$  momenta is also

1625 expected to provide discriminative power. Additional variables have been considered

1626 (e.g. signal kaon candidate momentum) but have not been retained because of the

1627 correlations they show with other variables.

1628 These kinematic variables are:

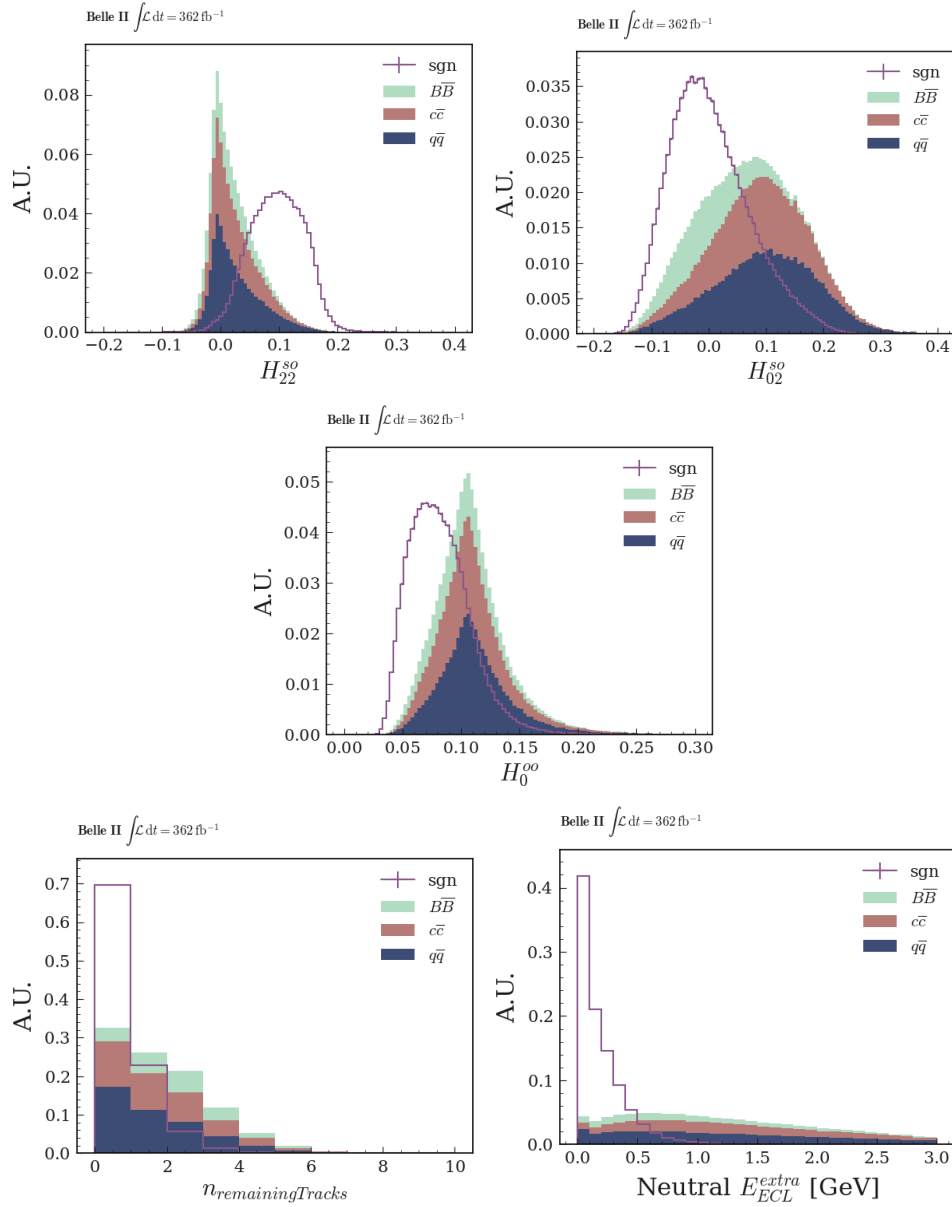

Figure 5.1: Distribution of the general event variables used in the classification. The Kakuno-Super-Fox-Wolfram moments (first two rows), the number of tracks remaining in the event after the  $\mathcal{T}(4S)$  reconstruction (bottom left) and the extra energy in the event  $NE_{ECL}^{\text{Extra}}$  (bottom right), for the different simulated samples.

- 1629 • The cosine of the angle between the kaon candidate three-momentum and the  
1630 thrust axis of the ROE,  $\cos(\theta_{Bthr})$ , computed in the CMS. We see in [Figure 5.2](#)  
1631 that the distribution of this variable is mostly uniform in signal events. This  
1632 is due to the fact that, in signal events, the momentum of the signal kaon is  
1633 not correlated to the momentum of the ROE.
- 1634 • The recoil mass of the kaon associated to the signal  $B$ -meson candidate.

### 1635 5.4.1.3 D meson identification variables

1636  $D$ -mesons decaying into a kaon and one or two pions contribute to the background  
1637 when said kaon is selected as the signal kaon candidate.

1638 To suppress such background, we reconstruct  $D$ -meson candidates using the signal  
1639 kaon candidate and ROE tracks, fitting them to a common vertex. Several  $D$  mesons  
1640 candidates are reconstructed in this manner and are ranked based on the p-value of  
1641 their vertex fit.

1642 Two hypotheses are retained for  $D$ -meson candidates:  $D^0$  candidates reconstructed  
1643 using the signal kaon candidate and one ROE track, and  $D^+$  candidates recon-  
1644 structed using the signal kaon candidate and two ROE tracks. The ROE tracks are  
1645 constructed using a pion hypothesis.

1646 The p-values of the best  $D$ -meson candidate in both categories are used as input  
1647 variables for the classifier, the corresponding distributions are shown in [Figure 5.3](#).

### 1648 5.4.1.4 Variables related to missing quantities

1649 Finally, because a large fraction of the event 4-momentum is carried by the neutrino  
1650 pair in signal events, we expect variables related to the event missing observables  
1651 (missing energy or momentum) to be strongly discriminative. We also expect some

Figure 5.2: Distributions of the kinematic variables used in the training of the classifier. The cosine of the angle between the kaon candidate three-momentum and the thrust axis of the ROE (left) and the recoil mass of the  $B_{sig}$  candidate (right).

background events to display similar missing quantities as a result of particles travelling outside the detector acceptance or being ineffectively detected, as well as long-lived neutral particles leaving the detector without interacting before eventually decaying.

The features computed using missing quantities in the event are:

- The angle between the missing momentum and the signal kaon candidate momentum computed in the CMS,  $\phi^*(K, p_{miss})$ , computed in the CMS frame and defined as:

$$\cos(\phi^*(K^+, p_{miss})) = \frac{\mathbf{p}_K \cdot \mathbf{p}_{miss}}{|\mathbf{p}_K| |\mathbf{p}_{miss}|} \quad (5.6)$$

With  $\mathbf{p}_K$  the signal kaon candidate momentum.

- The sum of the missing energy and momentum in the event,  $E_{miss} + c\mathbf{p}_{miss}$ , computed in the CMS. Signal events are expected to have significantly higher missing energy and momentum than background events. The distributions of these variables are shown in [Figure 5.4](#).

#### 5.4.1.5 Features left out of the classifier training

The following features prove important for controls as well as for the interpretation of the measurement but are not used in the training of the classifier:

- The invariant mass of the neutrino pair, computed as:

$$q^2 = m_B^2 + m_K^2 - 2E_B E_K + 2\mathbf{p}_B \cdot \mathbf{p}_K, \quad (5.7)$$

where  $m_B$  and  $m_K$  correspond to the masses of the  $B^+$  and  $K^+$  mesons respectively, while  $E_B/\mathbf{p}_B$  and  $E_K/\mathbf{p}_K$  correspond to their energies/momenta.

Figure 5.3: Variables related to the  $D$ -meson identification: the p-value of the fit for  $D^0$  candidates (left) and  $D^+$  candidates (right).

1671 This is an important quantity, as  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$  exhibits a  $q^2$ -dependence.  
 1672 We can furthermore express  $q^2$  using reconstructed quantities:

$$q^2 \approx \frac{s}{4} + m_K^2 - \sqrt{s} E_K^* - 2\mathbf{p}_{tag} \cdot \mathbf{p}_K, \quad (5.8)$$

1673 where  $\sqrt{s}$  is the available energy in the collision event defined in Equation 2.1,  
 1674  $\mathbf{p}_{tag}$  is the momentum of the  $B_{tag}$  meson and  $E_K^*$  is the energy of the re-  
 1675 constructed signal candidate in the center-of-mass frame. This approximation  
 1676 assumes that the  $\Upsilon(4S)$  meson is approximately at rest in the center-of-mass  
 1677 frame, then  $\mathbf{p}_B = -\mathbf{p}_{tag}$  follows. In addition, using  $\sqrt{s}/2$  instead of  $m_B$   
 1678 allows to better reflect the variations of  $\sqrt{s}$  dependent on the experimental  
 1679 conditions.

- 1680 • The number of extra photons in the event  $N_\gamma$  corresponds to the number  
 1681 of photon candidates in the *ROE* of the event satisfying the requirements  
 1682 described in subsection 5.4.1.1. This variable is used to derive a correction  
 1683 to the most discriminative variable,  $NE_{ECL}^{extra}$ , detailed in Subsection 5.7.8.

## 1684 5.4.2 Event classification

1685 In this section, we describe the main selection step in this analysis. We classify  
 1686 events based on their signal-likeness using a gradient-boosted decision tree (BDT)  
 1687 based on XGBoost [102]. The working principle of binary classification as well as  
 1688 the way it is implemented in this analysis are described in Section 4.2.

1689 We detail in the following the way the classifier is built, trained and we measure its  
 1690 classification performance.

1691

Figure 5.4: Distribution of the variables related to the missing 4-momentum in the event:  $E_{miss}^* + p_{miss}^*$  (left), and  $\phi$  angle between the signal kaon and missing tri-momentum (right).

### 1692 5.4.3 Classifier training

1693 The classifier is built with the 13 variables described in [Subsection 5.4.1](#) and trained  
 1694 using the full simulated samples described in [Section 5.1](#). In order to keep overtrain-  
 1695 ing under control, the simulation sample is randomly split in halves, the classifier  
 1696 is then trained on both sub-samples simultaneously, using the other subsample to  
 1697 test the training (this corresponds to a 2-fold validation, which is discussed in [Sub-  
 1698 section 4.2.4](#)). The training sample is further split into signal (what the classifier  
 1699 has to identify), and background (containing the three types of background events:  
 1700  $B\bar{B}$ ,  $c\bar{c}$ ,  $q\bar{q}$ ). In the case of the testing sample, we conserve the information on the  
 1701 type of event, while the classifier is kept blind to it.

1702 As can be seen in [Figure 5.5](#) there is a good agreement between the output of the  
 1703 two trainings.

1704 It is possible, after performing the training, to estimate the gain brought by each  
 1705 feature. [Figure 5.7](#) shows the importance of each feature in the classification of  
 1706 the events. We see that some features bear a larger importance than others. Even  
 1707 though BDTs are typically good at handling correlations, we want to retain the  
 1708 minimum number of features needed to achieve good performance. This reduces  
 1709 correlations as well as the potential masking between variables. Because the feature  
 1710 importance can be tricky to interpret, it is useful to proceed by backwards elimina-  
 1711 tion to identify the best set of features to use.

1712 To do so, we train the classifier using  $n$  features, then train  $n - 1$  classifiers using as  
 1713 features the full set of variables to which a random variable is subtracted and pick  
 1714 the best set (that is, the one giving the lowest  $\mu_{sens}$  value evaluated on the testing  
 1715 sample, see [Section 4.3](#) for the definition of  $\mu_{sens}$ ), and so on and so forth.

1716 Finally, we transform the features to follow a uniform distribution which helps with  
 1717 shielding against outliers. The variables kept after this procedure are the ones de-  
 1718 scribed in [Subsection 5.4.1](#).

1719

### 1720 5.4.4 Classifier parameters

1721 Several parameters of the classifier impact its training:

- 1722 • The number of trees ( $n_T$ );
- 1723 • The maximum depth of each tree ( $d_T$ );
- 1724 • The learning rate ( $0 < \eta < 1$ );
- 1725 • The sampling rate ( $0 < \sigma < 1$ );
- 1726 • The positive/negative weights balance  $S_w$ .

1727 The  $\eta$  parameter shrinks feature weights after each boosting round in order to pre-  
 1728 vent overfitting, while  $\sigma$  corresponds to the fraction of the training sample used  
 1729 in each boosting round: for each round, the training procedure randomly samples

Figure 5.5: Classifier output for the two BDTs trained by splitting simulation samples in 2 and swapping training and testing sample.

1730  $\sigma \times n_{train}$  to use in the training, with the aim of reducing overfitting.  $S_w$  controls  
 1731 the balance of positive and negative weights for unbalanced classes.

1732 To optimally parameterize the classifier, we investigate different values for the  
 1733 parameters  $n_T$ ,  $\eta$  and  $\sigma$ . The tree depth is kept at a constant value  $d_T = 3$ , we  
 1734 also fix  $S_w = 10 \times n_{bkg}/n_{sgn}$ .

1735 We then aim at finding a  $(n_T; \eta; \sigma)$  set offering a good trade-off between classifier  
 1736 performance and overfitting. To do so, we make use of the `Optuna` package [111]  
 1737 to perform an optimization in the parameter space. `Optuna` allows one to auto-  
 1738 matically search for a given parameter space with the goal of minimizing a user-  
 1739 defined *objective* function. Here, the *objective* is defined as the  $\mu_{sens}$  defined in  
 1740 Section 4.3 evaluated on the testing sample. In order to monitor overfitting we  
 1741 compare this value to the  $\mu_{sens}$  computed for the validation sample. Figure 5.6  
 1742 shows the result of this optimization. We find an adequate set of parameters to be  
 1743  $(n_T = 1300, \eta = 0.03, \sigma = 0.8)$ .

1744 Figure 5.8 shows a good trade-off between classifier output performance and  
 1745 overfitting. The values chosen for each parameter of the classifier can be found in  
 1746 Table 5.2.

## 1747 5.5 Signal search region

1748 After training and optimizing the classifier, we now aim at defining a region, based  
 1749 on the classifier output, on which the binned-likelihood model defined in Section 4.4  
 1750 will be applied to data to measure the value of  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$ . In Subsection 5.5.1  
 1751 we describe how this signal region (SR) is defined. In Subsection 5.5.2 we study

Figure 5.6: Distribution of the estimated  $\mu_{sens}$  for each  $(n_T; \eta; \sigma)$  combination.

Figure 5.7: Importance of the 13 features used in the training of the classifier.

Figure 5.8: Training-testing agreement for signal (red) and background (blue) samples and Area Under the Curve (AUC) for our choice of classifier parameters.

Parameter	Value
Number of trees ( $n_T$ )	1300
Tree depth ( $d_T$ )	3
Shrinkage ( $\eta$ )	0.03
Sampling rate $\sigma$	0.8
Positive/negative weights balance ( $S_w$ )	1

Table 5.2: Hyperparameters of the classification model used in the analys.

1752 the contribution of each event types to the SR using simulated samples and we  
 1753 characterize the leading sources of background contributions.

### 1754 5.5.1 Definition

1755 We define the signal search region based on a requirement on the classifier output  
 1756 value. This value is taken to correspond to about 60% signal selection efficiency after  
 1757 the pre-selection described in previous sections. In the end, in the SR the signal  
 1758 selection efficiency is  $\sim 0.40\%$ . This selection corresponds to a lower threshold  
 1759 requirement on the classifier output value  $BDT > 0.4$ . The region is divided in  
 1760 6 equal bins of classifier output value. The comparison between data yields and  
 1761 expected yields from simulation in these bins will be the primary input in the binned-  
 1762 likelihood model to measure  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$ .

1763 [Table 5.3](#) shows the signal selection efficiency at different stages of the selection.

### 1764 5.5.2 Simulation study

1765 We use the simulated samples described in [Section 5.1](#) to study the expected be-  
 1766 havior of the SR. [Figure 5.9](#) shows the expected signal and background yields in the  
 1767 SR for an integrated luminosity of  $360 \text{ fb}^{-1}$ . The classifier output distribution is,  
 1768 by construction, flat for the signal contribution. This allows to easily treat classifier

Figure 5.9: Distribution of  $B^+ \rightarrow K^+ \nu \bar{\nu}$  candidates in the whole classifier output range (left) and signal search region (right) obtained in simulated (filled histograms) generic background and (grey line) corresponding signal samples. The expectations are provided for  $L = 362 \text{ fb}^{-1}$ . The signal expectation is magnified by a factor of 10 for better visibility.

Selection stage	$\varepsilon_{sig} (\times 10^{-2})$
Hadronic FEI selection	$2.482 \pm 0.002$
Basic event selection	$0.6598 \pm 0.0011$
Signal search region	$0.3996 \pm 0.0009$

Table 5.3: Signal selection efficiency at various stages of the selection. The uncertainties quoted are statistical only.

1769 output bins as signal efficiency quantile regions.

1770 We expect the three background contributions ( $B\bar{B}$  pairs,  $c\bar{c}$  and light  $q\bar{q}$ ) to pop-  
 1771 ulate the lower classifier output bins, with  $q\bar{q}$  events only populating the first SR  
 1772 bins. In addition, we see that the lower threshold defining the SR allows to discard  
 1773 most of the  $q\bar{q}$  contribution.

1774 Almost all of the background contamination in the last SR bins comes from  $B\bar{B}$   
 1775 pair events. [Subsection 5.5.3](#) describes the study and classification of these events  
 1776 in simulation. Here, the simulated  $B\bar{B}$  events are classified according to the gener-  
 1777 ated decays of both  $B$  mesons, as several factors can fake the signal signature.

1778

### 1779 5.5.3 Background composition in the signal region

1780 The  $B\bar{B}$  events populating the signal region are classified and counted in order to  
 1781 assess the main contributions to the  $B\bar{B}$  sample yields.

1782 Because the selection is based on the tagging method described in [Section 4.1](#), signal  
 1783 events are of the type  $\Upsilon(4S) \rightarrow B^+(K^+ \nu \bar{\nu}) B^-(X)$ , where  $X$  corresponds to one of  
 1784 the decays listed in [Table 4.1](#). Several issues can lead to a  $B\bar{B}$  event being wrongfully  
 1785 selected as signal (misidentification of the signal  $K^+$ , wrong reconstruction of the

$B$ -meson decay category	Requirements
$Dn\pi$	One $B$ daughter is in the <b><math>D</math></b> class, the other daughters are in the <b><math>n\pi</math></b> class.
$D\ell\nu$	$B$ has 3 daughters. One is in the <b><math>D</math></b> class, one is in the <b><math>\ell</math></b> class and one is in the <b><math>\nu</math></b> class.
$D\tau\nu$	$B$ has 3 daughters. One is in the <b><math>D</math></b> class, one is in the <b><math>\tau</math></b> class and one is in the <b><math>\nu</math></b> class.
$D$ Hadrons	One $B$ daughter is in the <b><math>D</math></b> class, the other daughters are in the <b>Hadrons</b> class.
$DD$	$B$ has 2 daughters. Both are in the <b><math>D</math></b> class.
$n\pi\ell\nu$	One $B$ daughter is in the <b><math>\ell</math></b> class, one is in the <b><math>\nu</math></b> class and the others are in the <b><math>n\pi</math></b> class.
$K^+K^0K^0$	$B$ has 3 daughters. One is a $K^+$ , the others are $K^0/\bar{K}^0$ .
$c\bar{c}$	At least one $B$ daughter is in the <b><math>c\bar{c}</math></b> class.
Hadrons	All $B$ daughters are in the <b>Hadrons</b> class.

Table 5.4:  $B$ -meson decay categories used to classify the  $B\bar{B}$  background events. The categories are mutually exclusive (a given  $B\bar{B}$  event cannot be present in different categories). The different classes, written in bold, are defined in [Appendix D](#).

1786  $B_{tag}$ ). Because of this, both  $B$ -mesons in  $e^+e^- \rightarrow Upsilon(4S)$  events need to be  
1787 studied to understand the composition of the background in the SR. We decide to  
1788 classify  $B$ -mesons decays in several categories described in [Table 5.4](#), the prevalence  
1789 of  $B\bar{B}$  background in the SR is then studied in simulated samples, based on these  
1790 categories (see [Table 5.5](#) and [5.6](#)).

1791 Around 90% of the  $B\bar{B}$  contribution to the SR comes from charged  $B^+B^-$   
1792 pairs. The main overall background contribution ( $\simeq 50\%$  of all charged  $B\bar{B}$  yields)  
1793 comes from events where one  $B$  meson decays semileptonically as  $B \rightarrow D^{(*)}\ell\nu$ , with  
1794 ( $\ell = e, \mu$ ) and the other  $B$  meson decays into a final state composed of several pions  
1795 and a  $D$ -meson. In these cases, a kaon from the  $D$  meson decay is selected as the  
1796 signal kaon, while the undetected neutrino in the event, potentially associated to an  
1797 additional particle travelling outside the detector acceptance, mimics the missing  
1798 energy expected in the signal.

1799 Because of their prevalence, these decays motivate the development of the  $D$  meson  
1800 suppression variables described in [Subsection 5.4.1](#).

1801 In addition, several decays are expected to populate the signal region because they  
1802 inherently show the same experimental signature as the signal. This includes the  
1803  $B^+ \rightarrow K^+n\bar{n}$  and  $B^+ \rightarrow K^+K_L^0\bar{K}_L^0$  decays. We further discuss these in [Subsec-](#)  
1804 [tion 5.7.5](#) and [Subsection 5.7.6](#).

$B^+B^-$ event type	occurrence (%)
misidentified $K_{sig}$	3.42%
$Dn\pi + D\ell\nu$	50.34%
$Dn\pi + Hadrons$	4.97%
$Dn\pi + c\bar{c}$	3.84%
$D\ell\nu + D\ell\nu$	3.77%
$Dn\pi + K^+K^0K^0$	3.69%
$D\ell\nu + DHadrons$	3.54%
$D\ell\nu + DD$	2.94%
$Dn\pi + D\tau\nu$	2.86%
$Dn\pi + DHadrons$	2.86%
$D\ell\nu + c\bar{c}$	2.64%
$Dn\pi + Dn\pi$	2.03%
$Dn\pi + DD$	0.98%
$D\ell\nu + D\tau\nu$	0.90%
$D\ell\nu + Hadrons$	0.60%
$c\bar{c} + DD$	0.45%
$c\bar{c} + Hadrons$	0.45%
$DHadrons + DHadrons$	0.45%
$DHadrons + Hadrons$	0.45%
$D\tau\nu + c\bar{c}$	0.30%
$K^+K^0K^0 + c\bar{c}$	0.23%
$DD + DHadrons$	0.23%
$D\tau\nu + DHadrons$	0.15%
$K^+K^0K^0 + DD$	0.15%
$DD + Hadrons$	0.15%
$D\ell\nu + K^+K^0K^0$	0.08%
$n\pi\ell\nu + c\bar{c}$	0.08%
$D\tau\nu + DD$	0.08%
$K^+K^0K^0 + DHadrons$	0.08%
$c\bar{c} + c\bar{c}$	0.08%
$c\bar{c} + DHadrons$	0.08%
$Hadrons + Hadrons$	0.08%
other	10.12%

Table 5.5: Prevalence of simulated  $B^+B^-$  decays in the signal region of the analysis. Precisions on the naming scheme can be found in [Appendix D](#). The "misidentified  $K_{sig}$ " category corresponds to the percentage of events where the identified signal  $K^+$  is not a generated  $K^+$ .

$B^0 \bar{B}^0$ event type	occurrence (%)
misidentified $K_{sig}$	10.14%
$Dn\pi + D\ell\nu$	41.13%
$Dn\pi + DHadrons$	10.48%
$D\ell\nu + D\ell\nu$	6.45%
$D\ell\nu + cc$	4.03%
$D\ell\nu + DD$	4.03%
$D\ell\nu + Hadrons$	3.23%
$Dn\pi + Hadrons$	2.42%
$D\ell\nu + DHadrons$	2.42%
$DHadrons + DHadrons$	2.42%
$Dn\pi + Dn\pi$	1.61%
$Dn\pi + D\tau\nu$	1.61%
$Dn\pi + cc$	1.61%
$Dn\pi + DD$	1.61%
$DHadrons + Hadrons$	1.61%
$D\ell\nu + D\tau\nu$	0.81%
$D\tau\nu + DHadrons$	0.81%
$D\tau\nu + Hadrons$	0.81%
$cc + Hadrons$	0.81%
$DD + Hadrons$	0.81%
other	10.14%

Table 5.6: Prevalence of simulated  $B^0 \bar{B}^0$  decays in the signal region of the analysis. Precisions on the naming scheme can be found in [Appendix D](#). The "misidentified  $K_{sig}$ " category corresponds to the percentage of events where the identified signal  $K^+$  is not a generated  $K^+$ .

## 1805 5.6 Simulation validation using control channels

1806 Every step of the analysis described up to this point has been developed using sim-  
1807 ulated samples. Considerable efforts have been put into the development of the  
1808 different tools described in [Section 2.6](#), with the ultimate goal of accurately de-  
1809 scribing the physical processes and detector interactions in the Belle II experiment.  
1810 However, small but potentially harmful discrepancies might exist between measured  
1811 data and simulation. In order to ensure a reliable estimation of the desired param-  
1812 eters, it is essential to identify and correct such discrepancies.

1813 In this section, we investigate the agreement between data and simulation through-  
1814 out the analysis process. However, we cannot measure and correct potential effects  
1815 directly on events that populate the analysis' signal region, as we could introduce  
1816 bias to the result. To avoid biases, we need to define several *control samples* to  
1817 be studied in both simulation and data on which to gauge the robustness of the  
1818 selection process without unblinding our signal sample:

- 1819 • We check the efficiency of signal selection using modified  $B^+ \rightarrow K^+ J/\psi$  events  
1820 reconstructed in data and simulation. We describe in [Subsection 5.6.1](#) the  
1821 process through which these events are modified to mimic our signal signature.
- 1822 • We check the agreement between off-resonance data and  $q\bar{q}$  simulation of  
1823 the distributions of the classifier features in [Subsection 5.6.2](#). Off-resonance  
1824 data are expected to behave similarly to  $q\bar{q}$  continuum. In addition, the off-  
1825 resonance data sample size ( $42 \text{ fb}^{-1}$  of integrated luminosity) allows to shield  
1826 this study against too much statistical fluctuations (which is a limitation in  
1827 the study of the other control samples). We also describe how we improve  
1828 data-simulation agreement for  $q\bar{q}$  events by building an additional classifier  
1829 trained on off-resonance data.
- 1830 • Finally, we check data/simulation agreement for the entire background con-  
1831 tribution (continuum  $q\bar{q}$  and  $B\bar{B}$  coming from  $\mathcal{T}(4S)$  production) in signal  
1832 sidebands. We define several signal sidebands, described in [Subsection 5.6.3](#).  
1833 These samples all consist in on-resonance data passing the signal selection  
1834 with some requirements being inverted to assure that contamination from ac-  
1835 tual signal is kept to a minimum. It is optimal to construct several sideband  
1836 samples, fully orthogonal to each other, to identify and decouple potential  
1837 simulation issues.

1838

### 1839 5.6.1 Signal efficiency validation in embedded $B \rightarrow K^+ J/\psi$ events

1840 We want to validate the behavior of signal events in the analysis using data events,  
1841 without unblinding actual signal candidates.

1842 To do so, we use three different samples: simulated signal events, simulated  $B^+ \rightarrow$   
1843  $K^+ J/\psi$  events and reconstructed  $B^+ \rightarrow K^+ J/\psi$  events. Specifically, we restrict the  
1844 selection to events with  $J/\psi \rightarrow \mu^+ \mu^-$ . This decay is considered because it is rather  
1845 easily reconstructed and shares kinematic similarities with our signal. The steps of  
1846 the method are enumerated below.

- 1847 1. Events containing a  $B^+ \rightarrow K^+ J/\psi$  decay in data and simulated samples are  
1848 identified and selected.
- 1849 2. All objects associated with the selected  $B^+ \rightarrow K^+ J/\psi$  decay are removed,  
1850 keeping only the ROE, which contains the decay product of the accompanying  
1851  $B^-$  meson when the  $B^+ \rightarrow K^+ J/\psi$  decay is correctly identified.
- 1852 3. Events containing a  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay are selected in signal simulated sam-  
1853 ples, and the same procedure is used to remove all objects *not* associated with  
1854 the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay in the events.
- 1855 4. The signal decay of step 3 is combined with the ROE of step 2 to form an  
1856 “embedded” event.
- 1857 5. Finally, the signal decay kinematics is adjusted to match the kinematics of  
1858 the original  $B^+ \rightarrow K^+ J/\psi$  decay. The reconstructed signal  $K^+$  is shifted  
1859 and rotated so that the position of the decay vertex and the direction of the  
1860  $B^+$  meson for the simulated signal  $B^+$  agree with those determined for the  
1861 reconstructed  $B^+ \rightarrow K^+ J/\psi$ .

1862 The *signal embedding* procedure is applied to both data and simulation:

- 1863 • A sample of 73651 events is used in simulation,
- 1864 • A sample of 7214 events is used in data.

1865 These events are then subjected to the reconstruction and selection described in  
1866 [Section 5.2](#). A sample of 112 (1709) candidates on data (simulation) are retained at  
1867 this stage. [Figure 5.10](#) shows the distributions of some of the BDT input variables  
1868 for the embedded simulated and data samples along with signal simulated events.  
1869 The distributions of all input variables are reported in [Appendix C](#).

1870 The embedded simulated sample reproduces the simulated signal well. We also  
1871 see an overall good agreement between the embedded data and simulation. The  
1872 classifier optimized for the signal search is run on the embedded samples, the output  
1873 distribution is reported in [Figure 5.11](#).

1874 [Table 5.7](#) presents the selection efficiencies for embedded samples after pre-  
1875 selection and after final selection. The efficiencies are normalized to the number of  
1876 events passing the embedding procedure (7214 for data and 73651 for simulation).

Figure 5.10: Distributions of the Kakuno-Super-Fox-Wolfram moment  $H_{02}^{s0}$  (top right), sum of missing energy and momentum computed in the CMS (bottom left) and sum of the extra energy in the calorimeter (bottom right) for simulated signal (light blue histogram), simulated embedded sample (red histogram), and embedded data (points). The distributions are normalized to the number of events in data. No best candidates selection is applied, distributions appear as they are input to the classifier.

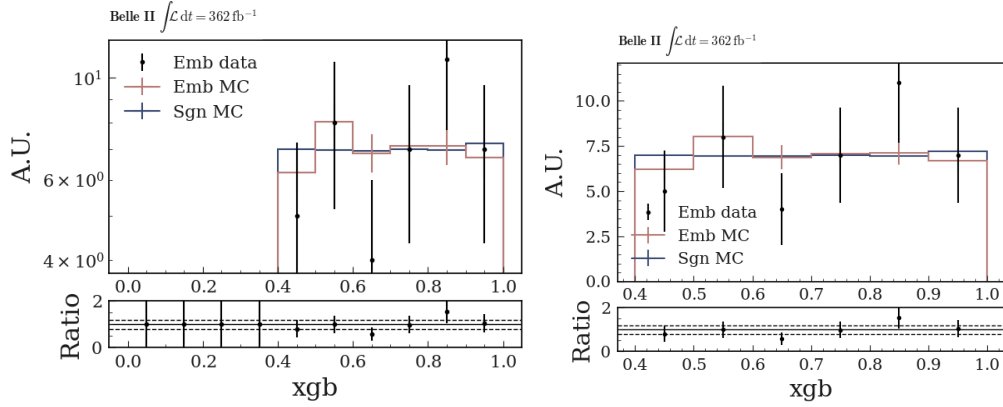

Figure 5.11: Classifier output distribution in the full range (left) and in signal region (right) for simulated signal (light blue histogram), simulated embedded sample (red histogram), and embedded data (points). The distributions are normalized to the number of events in data. Best candidate selection is applied.

1877 As shown in Table 5.7, the data-simulation ratio at pre-selection level is around 0.67  
 1878 and is consistent with the ratio found at the end of the selection. As a consequence,  
 1879 in the next steps of the analysis, 0.67 is used as calibration factor for the signal effi-  
 1880 ciency and an uncertainty of 16% (from the efficiency ratio in the BDT signal region  
 1881 after best candidate selection selection) will be considered as systematic uncertainty.

Sample	pre-selection	Signal search region
Data	$1.71 \pm 0.15\%$	$0.58 \pm 0.09\%$
Simulation	$2.51 \pm 0.06\%$	$0.96 \pm 0.04\%$
Ratio	$0.68 \pm 0.06$	$0.60 \pm 0.10$

Table 5.7: Selection efficiency in the signal region for the embedded data and simulated samples at different stages of the reconstruction and selection.

Figure 5.12: Distribution of modified  $M_{bc}$ . The off-resonance data is altered to mimic the on-resonance continuum. Distributions are normalized to the same number of events.

### 1882 5.6.2 $q\bar{q}$ background validation using off-resonance data

1883 After validating the behavior of signal events throughout the selection process, we  
 1884 want to verify whether the continuum simulation provides a good description of the  
 1885 off-resonance data. We use off-resonance data corresponding to  $42 \text{ fb}^{-1}$  of integrated  
 1886 luminosity.

1887 The background yield in the signal region is evaluated by using continuum sim-  
 1888 ulation. Indeed, a large part of the background contributions is continuum light  $q\bar{q}$   
 1889 and  $c\bar{c}$ . Generic simulated continuum samples can be corrected by comparing them  
 1890 to off-resonance data.

1891 This comparison relies on the assumption that the kinematic features of the contin-  
 1892 uum events do not appreciably depend on the beam energy. Instead some variables  
 1893 directly related to the beam energy should be modified accordingly to allow com-  
 1894 parisons. For this reason, the beam constrained mass of the  $B_{tag}$  candidate,  $M_{bc}$ , is  
 1895 modified in the off-resonance sample to mimic the on-resonance distribution:

$$\tilde{M}_{bc} = \sqrt{\left(\frac{E_{ON}^*}{2}\right)^2 - \left(\frac{E_{ON}^*}{E^*} \cdot p_{B_{tag}}^*\right)^2}, \quad (5.9)$$

1896 where  $E_{ON}^*$  is the nominal beam energy in the on-resonance data (10.58 GeV) in the  
 1897 CMS,  $E^*$  is the beam energy of the considered event in the CMS and  $p_{B_{tag}}^*$  is the  
 1898 momentum of the  $B_{tag}$  in the CMS. After this, the data-simulation comparison for  
 1899  $M_{bc}$  is shown in Figure 5.12. We use the total off-resonance data sample, as well as  
 1900 the simulated continuum sample corresponding to  $1 \text{ ab}^{-1}$  of integrated luminosity.

1901 The data-simulation agreement for the classifier input variables distributions is  
 1902 quite satisfactory. The distribution of the most discriminative variable related to  
 1903 missing quantities,  $E_{miss}^* + cp_{miss}^*$ , is shown in Figure 5.13 (top). Nevertheless, an  
 1904 event-by-event correction is further applied: a classifier (noted  $\text{BDT}_c$ ) is trained af-  
 1905 ter the preselection (with a relaxed selection on the modified  $M_{bc}$ :  $\tilde{M}_{bc} > 5.23 \text{ GeV}/c^2$ )

Figure 5.13: Distributions of  $E_{miss}^* + p_{miss}^*$  for off-resonance data and continuum simulation before (top) and after (bottom)  $\text{BDT}_c$  reweighting. Distributions are normalized to the same number of events.

1906 using the off-resonance data as signal and the continuum simulation as background.  
 1907 The input variables are the same as in the main classifier described in [Subsec-](#)  
 1908 [tion 5.4.2](#), except for  $M_{bc}$ , which is removed. The  $\text{BDT}_c$  classifier provides as output  
 1909 a factor  $p$  per candidate and a correction weight  $p/(1-p)$  is applied on a candidate-  
 1910 by-candidate basis to the simulated continuum events. The result is an improved  
 1911 agreement, as shown in [Figure 5.13](#) (bottom). The data/simulation comparison of  
 1912 all the other variables used as input for the main classifier are shown in [Appendix B](#)).

1913 After the reweighting and the tighter selection cut  $\tilde{M}_{bc} > 5.27 \text{ GeV}/c^2$ , the  
 1914 overall data-simulation ratio is equal to  $0.82 \pm 0.01$ . This value is used to reweight  
 1915  $c\bar{c}$  and light  $q\bar{q}$  events before the main classifier training (see [Section 5.4](#)). The  
 1916 same ratio, computed after the classifier output selection described in [Section 5.5](#)  
 1917 and best candidate selection, is equal to  $1.5 \pm 0.5$ . This is consistent with the  
 1918 correction factor obtained at pre-selection level. For this reason, 0.82 is kept as a  
 1919 normalization factor for the continuum component in the rest of the analysis and a  
 1920 50% uncertainty, coming from the data-simulation ratio computed in the classifier  
 1921 signal region, is assigned to this correction.

### 1922 5.6.3 Background validation using on-resonance data

1923 Finally, the data-simulation agreement for the input variables for both continuum  
1924 and  $Y(4S)$  samples is performed on on-resonance data. To be sure to comply with  
1925 the blinding procedure described in [Section 4.7](#), we aim at defining control samples  
1926 with as few pollution from our signal as possible, we identify:

- 1927 • A wrong  $B$ -meson charge sideband: the signal kaon and  $B_{tag}$  are requested to  
1928 have the same charge.
- 1929 • A particle ID sideband: the signal kaon is requested to have  $kaonID > 0.1$  and  
1930  $pionID > 0.5$ .

1931 These sideband samples are built using the particle identification methods described  
1932 in [Subsection 2.7.2](#). In these sidebands, the  $B\bar{B}$  simulated samples are corrected in  
1933 normalization with the overall factor extracted from the embedding procedure (0.67,  
1934 see [Subsection 5.6.1](#)). The  $q\bar{q}$  and  $c\bar{c}$  simulated samples are corrected by using the  
1935 off-resonance data, both in the normalization, with a factor 0.82, and in the shape  
1936 of the distributions with the candidate by candidate weights obtained with the use  
1937 of the  $BDT_c$  (see [Subsection 5.6.2](#)).

1938 The sideband data and simulation samples are processed through the nominal  
1939 classifier of the analysis. The classifier output restricted to the signal region is shown  
1940 in [Figure 5.14](#). On the top panel, a comparison of the simulation between sideband  
1941 and nominal samples is shown. On the bottom panel, data-simulation comparison  
1942 in each sideband is reported.

1943  
1944 From these samples, data/simulation ratios are computed to correct potential  
1945 remaining discrepancies: ratios of  $1.6 \pm 0.6$  for the wrong  $B$ -meson charge sideband  
1946 and  $1.24 \pm 0.27$  for the particle ID sideband are found. These ratios agree with each  
1947 other and are compatible with unity, meaning that the corrections already applied  
1948 on  $B\bar{B}$  and  $q\bar{q}$  cover data-simulation differences. Therefore, no further correction is  
1949 applied on the general background normalization. The relative uncertainties on the  
1950 ratios are 38% for the wrong  $B$ -meson charge and 22% for the particle ID control  
1951 samples. Finally, a 30% uncertainty on the  $B\bar{B}$  component normalization is assigned  
1952 as systematic uncertainty.

Figure 5.14: (top) Classifier output in the BDT signal region for nominal and side-band simulation and (bottom) data-simulation comparison in the BDT signal region. The distributions on top are normalized to unity. While the distributions on bottom are normalized to the same number of events. Wrong charge sideband is on the left, kaonID sideband is on the right.

## 1953 5.7 Systematic uncertainties

1954 In this section, we describe how we evaluate the different systematic uncertainties that  
 1955 enter the measurement of  $\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu})$ . These systematic uncertainties affect  
 1956 the likelihood model described in [Section 4.4](#) through a set of nuisance parameters,  
 1957 which cause variations with respect to expectations in the bins of the signal region.

1958 Systematic uncertainties come from physical processes mismodelling and detec-  
 1959 tor interaction mismodelling. The uncertainties considered in the statistical model  
 1960 are:

- 1961 • Particle ID selection modeling uncertainty for the signal  $K^+$ , described in  
 1962 [Subsection 5.7.1](#).
- 1963 • Tracking efficiency modeling. Detailed in [Subsection 5.7.2](#), this is only relevant  
 1964 for the signal kaon track, as tracking modeling is already taken into account  
 1965 for the FEI reconstructed  $B_{tag}$ .
- 1966 • Branching fractions of the leading  $B^0$  and  $B^+$  background decays, which are  
 1967 varied according to their PDG uncertainties. Described in [Subsection 5.7.3](#),  
 1968 furthermore [Subsection 5.5.3](#) provides a detailed categorisation of these decays.
- 1969 • Form factor uncertainties derived from Ref. [34] (Detailed in [Subsection 5.7.4](#)).
- 1970 • Modeling of the low-multiplicity decay  $B^+ \rightarrow K^+n\bar{n}$  involving neutrons and  
 1971 kaons in the final state. A study on this background is described in [Subsec-  
 1972 tion 5.7.5](#).
- 1973 • Modeling of the signal-like  $B^+ \rightarrow K^+K^0\bar{K}^0$  decay, described in [Subsec-  
 1974 tion 5.7.6](#).
- 1975 • Branching fractions of  $B$ -mesons decays to excitations of  $D$ -mesons ( $D^{**}$ ), as  
 1976 discussed in [Subsection 5.7.7](#).
- 1977 • Correction on the number of photon in the event to mitigate data/simulation  
 1978 discrepancies. This is described in [Subsection 5.7.8](#).
- 1979 • Difference between simulation and data embedded samples for the signal se-  
 1980 lection efficiency study. The correction factor derived in [Subsection 5.6.1](#) is  
 1981 applied. Due to a small sample size it is not possible to derive a normalization  
 1982 variation from the control sample but an uncorrelated bin-by-bin variation on  
 1983 the efficiency correction, according to its error, is allowed.
- 1984 • The number of  $B\bar{B}$  events used as input in the measurement of  $\mathcal{B}(B^+ \rightarrow$   
 1985  $K^+\nu\bar{\nu})$ , which corresponds to  $387.1 \times 10^6$  pairs with an uncertainty of 1.5%.  
 1986 For the continuum normalization, cross section and luminosity are needed.  
 1987 The uncertainty on the latter is computed centrally for the whole collabora-  
 1988 tion and is of the order of 1%, we consider this to be included in the overall  
 1989 continuum normalization factors.

- 1990 • Background contributions from  $B$ -meson decays involving a direct  $K^+$  produc-  
1991 tion. These become prevalent in the high sensitivity area of the signal search  
1992 region. Out of these decays,  $B^+ \rightarrow K^+ D^{(*)0/-}$  are of particular interest due  
1993 to a relevant and less-known fraction of charmed mesons decays involving  $K_L^0$   
1994 mesons [112]. These decays are studied in the particle ID sideband described  
1995 in [Subsection 5.6.3](#), and are scaled by  $30\%(\pm 10\%)$ .
- 1996 • Uncertainty on the estimated background yield and background shape: for  
1997  $c\bar{c}$  and light  $q\bar{q}$  a 45% uncertainty in the normalization is considered, coming  
1998 from the BDT reweighting described in [Subsection 5.6.2](#). In addition, for  
1999 the  $B\bar{B}$  component, a normalization uncertainty of 30% is applied (details in  
2000 [Subsection 5.6.3](#)).
- 2001 •  $K_L^0$  reconstruction efficiency, studied centrally by the Belle II collaboration.  
2002 From these studies, we derive a 17% uncertainty all signal and background  
2003 components.

### 2004 5.7.1 Particle identification

2005 One source of systematic uncertainty comes from the particle identification require-  
2006 ment to select the signal kaon candidate. Simulated events (signal and background  
2007 alike) are given a weight correcting for discrepancies between data and simulation  
2008 particle identification. These weights are provided by the Belle II performance group  
2009 for a collaboration-wide use. The PID weights are defined in bins of  $p_T$  (transverse  
2010 momentum) and  $\cos(\theta)$  (cosine of the polar angle of the associated track) of the  $K^+$   
2011 candidate. In addition, uncertainties on the weights values are also provided, they  
2012 are then propagated to our statistical model:

- 2013 • For each event  $e$  present in the signal region, a series of 500 replicas  $i$  are pro-  
2014 duced following the method described in [Subsection 4.5.1](#), computing modified  
2015 PID weights values based on the associated PID weight uncertainty.
- 2016
- 2017 • From sums of the PID weights for each event category and signal region bin,  
2018 the covariance matrix  $C_{PID}$  is computed as described in [Subsection 4.5.2](#). A  
2019 representation of  $C_{PID}$  can be seen in [Figure 5.15](#).
- 2020
- 2021 • The Single Value Decomposition method described in [Subsection 4.5.2](#) is used  
2022 to identify the three eigenvectors associated to the three largest eigenvalues  
2023 of  $C_{PID}$ . Each eigenvector is then added to the likelihood model with an  
2024 associated nuisance parameter  $\theta_i^{PID}$ ,  $i = 1, 2, 3$ .
- 2025 • The remaining elements of  $C_{PID}$  decomposition (see [Equation 4.24](#)) are added  
2026 in quadrature to the uncorrelated systematic uncertainties shown in [Subsec-  
2027 tion 5.8.1](#).

Figure 5.15: Correlation matrix between the expected yields in the different signal region bins. The signal search region is composed of 6 bins, the expected yields are observed in 4 simulated samples (3 background samples and 1 signal sample), thus the matrix is of size  $24 \times 24$ . The left figure shows the original correlation matrix, while the right figure shows an approximation of said matrix obtained by a truncation of the covariance eigen-decomposition described in Equation 4.24. Here, the 3 eigenvectors associated to the 3 largest eigenvalues are used for the decomposition.

### 2028 5.7.2 Tracking efficiency

2029 A systematic uncertainty comes from a possible inaccurate modeling of the track  
 2030 finding efficiency in simulation. As mentioned before, this effect only needs to be  
 2031 estimated for the reconstructed tracks taken as the signal  $K^+$  candidate, as the  
 2032 tracking efficiency uncertainty is already taken into account for the other tracks in  
 2033 the event through the FEI algorithm. Following guidelines from dedicated studies  
 2034 performed by the Belle II tracking group [113], we assign an uncertainty of 0.9%  
 2035 on the track-finding efficiency which translates to a 0.9% uncertainty on the signal  
 2036 normalization introduced in the model.

### 2037 5.7.3 Branching fraction of leading backgrounds

2038 One source of uncertainty comes from the measurement of the  $B$  meson decays  
 2039 making up the  $B\bar{B}$  background. The generalities about the signal region background  
 2040 composition have been described in Section 5.5. The study described here is based  
 2041 on the full  $B\bar{B}$  sample described in Section 5.1.

2042 The associated uncertainty arises from the values of the branching ratios used to  
 2043 generate such decays in the simulation. To account for this uncertainty, we derive  
 2044 nuisance parameters in the likelihood model by varying the branching ratios values of  
 2045 the decays populating the signal region, based on their nominal values and associated  
 2046 uncertainties taken from [66]. The uncertainties on the branching ratios values are  
 2047 then propagated to the likelihood model as follows:

- 2048 1. A set of branching ratios and associated uncertainties corresponding to the

- 2049 leading  $B\bar{B}$  decays in the signal region is created.  $\sim 80\%$  of  $B^\pm$  decays and  
 2050  $\sim 60\%$  of  $B^0/\bar{B}^0$  decays appear in this set.
- 2051 2. For each event  $e$  present in the signal region, a series of 1000 replicas  $i$  are cre-  
 2052 ated. For each replica, a modified branching ratio value  $Br_{i,n}(e)$  is computed  
 2053 from  $Br_n(e)$  with associated weights  $w_{i,n}^e$  as described in [Subsection 4.5.1](#),  
 2054 where  $n \in \{0, 1\}$  corresponds to the index of the  $B$  meson considered in the  
 2055 pair and  $Br_n(e)$  is the nominal value of the branching ratio for the decay of the  
 2056  $B$  meson considered. Decays not present in the set of decays studied are  
 2057 assigned a weight of 1.  
 2058 Finally, for each replica, a single weight  $w_i^e$  is computed as :  $w_i^e = w_{i,0}^e * w_{i,1}^e$ .
  - 2059 3. The bins of the likelihood fit ([Subsection 5.8.1](#)) are filled with the replicas  
 2060 according to the bin value of  $e$ . The end result is an array of 6 elements. Each  
 2061 element contains an array  $S_j, j \in \{1, \dots, 6\}$  of 1000 values, corresponding to the  
 2062 number of counts to the associated bin observed in a replica.
  - 2063 4. The bin-by-bin covariance is computed over the  $N = 1000$  replicas as described  
 2064 in [Subsection 4.5.2](#)
  - 2065 5. Three eigenvectors of the covariance matrix corresponding to the three largest  
 2066 eigenvalues are used to define variation vectors (see [Subsection 4.5.2](#) and [4.4](#)),  
 2067 each variation vector is incorporated in the likelihood model with an associated  
 2068 nuisance parameter.

#### 2069 5.7.4 Signal form factors

2070 We described in [Section 1.3](#) how the Standard Model form factor  $f_+(q^2)$  is needed to  
 2071 compute the signal branching fraction as a function of  $q^2$ . However, the simulated  
 2072 signal events are generated based on a uniform phase space for the decay products.  
 2073 Thus, we introduce a correction to properly take the form factor contribution into  
 2074 account. This correction is then treated as an additional source of systematic un-  
 2075 certainty.

2076 The form factor  $f_+(q^2)$  has been parametrised using three real values  $\alpha = (\alpha_0, \alpha_1, \alpha_2)$   
 2077 with corresponding uncertainties  $\sigma = (\sigma_0, \sigma_1, \sigma_2)$ , for which the associated covari-  
 2078 ance matrix  $C_\alpha$  has been computed (*cf.* [Equation 1.25](#), [1.27](#), [1.28](#) and [1.29](#)). The  
 2079 uncertainties  $\sigma_i$  are then propagated to the statistical model:

- 2080 •  $C_\alpha$  is decomposed using the Single Value Decomposition method described in  
 2081 [Subsection 4.5.2](#) to extract the three unit uncertainty eigenvectors  $v_1, v_2, v_3$  as  
 2082 well as their respective eigenvalues  $e_1^2, e_2^2, e_3^2$ .

- 2084 • Modified form factors are then computed as  $f_+(q^2, \alpha + e_i \mathbf{v}_i)$

2085

Figure 5.16: Result of an exponential fit of  $M(p\bar{p})$  obtained in  $B^+ \rightarrow K^+p\bar{p}$  data from Ref [114].

- 2086 • The expected number of signal events in the  $i$ -th bin of the signal search region
- 2087 associated to a given  $\alpha$ ,  $N_i(\alpha)$  is computed.
- 2088 • The three form factor modified vectors,  $\delta_1, \delta_2, \delta_3$  are defined as:

$$\delta_i^{ff} = \begin{pmatrix} N_1(\alpha + \sigma_i) - N_1(\alpha) \\ N_2(\alpha + \sigma_i) - N_2(\alpha) \\ N_3(\alpha + \sigma_i) - N_3(\alpha) \\ N_4(\alpha + \sigma_i) - N_4(\alpha) \\ N_5(\alpha + \sigma_i) - N_5(\alpha) \\ N_6(\alpha + \sigma_i) - N_6(\alpha) \end{pmatrix}, \quad i = 1, 2, 3 \quad (5.10)$$

2089 with each coefficient corresponding to a bin of the signal search region.  
2090

- 2091 • The three modified vectors computed are added to the statistical model as
- 2092 described in Section 4.4 with their respective nuisance parameters  $\theta_i^{ff}$ .

2093 The variations due to this source of uncertainty are of the order of the percent.

### 2094 5.7.5 Modeling of $B^+ \rightarrow K^+n\bar{n}$

2095 The decay  $B^+ \rightarrow K^+n\bar{n}$  is of particular concern in this analysis. Because neu-  
2096 trons are stable and do not interact with the detector, they can easily mimic the  
2097 experimental signature of the neutrino pair present in the signal. In addition,  
2098 this decay has never been observed, even though its branching ratio can be pre-  
2099 dicted from isospin symmetry using  $B^+ \rightarrow K^+p\bar{p}$ , which has been measured to be  
2100  $\mathcal{B}(B^+ \rightarrow K^+p\bar{p}) = 6.7(\pm 0.5 \pm 0.4) \times 10^{-6}$ . The  $B^+ \rightarrow K^+n\bar{n}$  decay is modelled  
2101 according to the 3-body phase-space in the standard Belle II simulation. How-  
2102 ever, [114] shows that this decay is expected to be enhanced at the  $n\bar{n}$  threshold.

2103 In order to model this enhancement, the data taken from [114] are fitted as shown  
2104 in Figure 5.16. Afterwards, a dedicated 100.000 events  $B^+ \rightarrow K^+n\bar{n}$  sample is

Figure 5.17:  $M_{n\bar{n}}$  distribution in simulated  $B^+ \rightarrow K^+ n\bar{n}$  events. Red points indicate fit results from Figure 5.16, blue histogram corresponds to phase-space MC and the magenta histogram is obtained after applying threshold enhancement.

2105 produced and reweighted (from the original phase space modeling to the aforementioned fit), as seen in Figure 5.17. This enhancement has a significant impact on  
 2106 the background rejection.  
 2107

2108 This modification of the modeling for  $B^+ \rightarrow K^+ n\bar{n}$  events is propagated through  
 2109 the computation of the value of  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$  by reweighting the  $B^+ \rightarrow K^+ n\bar{n}$   
 2110 events in the  $B\bar{B}$  background sample.

2111 Furthermore, a systematic uncertainty corresponding to 100% of the correction is  
 2112 applied to cover potential additional mismodeling.

2113 The uncertainty is treated using a single correlated systematic uncertainty source  
 2114 that affects the  $B^+ B^-$  background. The way in which systematic sources are ac-  
 2115 counted for in the fit is summarised in Table 5.8, dominant sources are due to the  
 2116 uncertainty on the  $B\bar{B}$  normalization and the signal efficiency.

### 2117 5.7.6 Modeling of $B^+ \rightarrow K^+ K^0 \bar{K}^0$

2118 Similarly to  $B^+ \rightarrow K^+ n\bar{n}$ , the  $B^+ \rightarrow K^+ K^0 \bar{K}^0$  can also pollute the signal search  
 2119 region. Three final states from this decay need to be considered:  $B^+ \rightarrow K^+ K_L^0 K_L^0$ ,  
 2120  $B^+ \rightarrow K^+ K_S^0 K_L^0$ , and  $B^+ \rightarrow K^+ K_S^0 K_S^0$ .

2121  $K_L^0$  are a general issue in the search for  $B^+ \rightarrow K^+ \nu \bar{\nu}$  as they easily go undetected  
 2122 and create sources of missing energy. Decay modes with  $K_S^0$  also contribute to the  
 2123 background composition of the signal region for a similar reason, albeit to a lesser  
 2124 extent. In the Belle II simulation,  $B^+ \rightarrow K^+ K^0 \bar{K}^0$  are generated using the phase-  
 2125 space dependence of their branching ratios. An additional set of resonant modes are  
 2126 considered and treated independently. However, a more accurate prediction of the dif-  
 2127 ferential branching ratio for the  $B^+ \rightarrow K^+ K_S^0 K_S^0$  decay mode can be found in [115].  
 2128 Assuming isospin asymmetry, we expect the same behavior for the  $B^+ \rightarrow K^+ K_L^0 K_L^0$   
 2129 decay mode. We proceed to assign weights to the relevant events following the pre-  
 2130 scriptions from [115].

2131 Finally the  $B^+ \rightarrow K^+ K_S^0 K_L^0$  final state is treated separately since intermediate  
 2132 scalar resonances cannot decay to the CP odd  $K_S^0 K_L^0$  pair. In this case, weights are

Figure 5.18: Density of simulated  $B^+ \rightarrow K^+ K^0 \bar{K}^0$  events (without any selection) in bins of the invariant mass of the  $K^0 \bar{K}^0$  system. The blue histogram corresponds to events where the decay is simulated according to the phase space. The black histogram corresponds to the predictions of [115]. The red histogram shows the result of the reweighting of the simulated events. By construction, the red and black histograms exactly overlap.

2133 derived from the amplitude analysis described in [115].

2134 In the case of  $B^+ \rightarrow K^+ K_S^0 K_S^0$  and  $B^+ \rightarrow K^+ K_L^0 K_L^0$ , a binned reweighting proce-  
 2135 dure is used, based on the distribution of the invariant mass of the two-kaon system,  
 2136 in order to match expectations, as seen in Figure 5.18.

2137

2138 For the  $B^+ \rightarrow K^+ K_S^0 K_L^0$  final state, the decays are modelled as a sum of  
 2139  $B^+ \rightarrow K^+ \phi^0$  resonances and a non-resonant p-wave contribution described  
 2140 in [115]. The resonant contribution is taken directly from the Belle II simulation,  
 2141 checking the branching ratio value against the world average from [66]. The p-wave  
 2142 contribution is taken into account by applying weights (Figure 5.19) to the phase  
 2143 space simulation.

2144 Following this correction, the total expected simulated  $B\bar{B}$  sample yield in the  
 2145 signal region defined in Section 5.5 goes up by 0.81%

2146 The uncertainty associated to the correction is then estimated. For each  $BDT$  output  
 2147 bin  $i$  of the signal region, the relative uncertainty  $u_r(i)$  is computed as:

$$u_r(i) = \frac{\nu_B(i) - \nu_B^*(i)}{\nu_B(i)}, \quad (5.11)$$

2148 where  $\nu_B(i)$  is the expected  $B\bar{B}$  yield in the bin  $i$  before the correction and  $\nu_B^*(i)$   
 2149 is the expected  $B\bar{B}$  yield for the same bin after the correction. The uncertainty is  
 2150 then propagated to the statistical model through a vector  $\mathbf{U}$  containing the correlated  
 2151  $u_r(i)$  as described in Section 4.4 with an associated nuisance parameter  $\theta^{3K}$ .

Figure 5.19: Amplitude squared for the p-wave contribution as a function of  $K^+K^-$  invariant mass. Based on [115].

### 2152 5.7.7 Modeling of $B \rightarrow D^{**} + X$ decays

2153 As shown in Subsection 5.5.2, the main background contribution in the signal  
 2154 search region comes from  $B\bar{B}$  pairs where at least one  $B$ -meson decays as  $B \rightarrow$   
 2155  $D^{(*)}/(**)+X$ . The cases including  $D^{**}$  mesons are especially problematic, as they  
 2156 are less known experimentally and are handled by PYTHIA [84] (here,  $D^{**}$  refers to  
 2157 one of the following excited states:  $D_0^*(2300)^+$ ,  $D_0^*(2300)^0$ ,  $D_1^*(2420)^+$ ,  $D_1^*(2420)^0$ ,  
 2158  $D_1(H)^+$ ,  $D_1^*(2430)^0$ ,  $D_2^*(2460)^+$ ,  $D_2^*(2460)^0$ ,  $D_{s0}^*(2317)^+$ ,  $D_{s1}^*(2536)^+$ ,  $D_{s1}^*(2460)^+$   
 2159 and  $D_{s2}^*(2573)^+$ ).

2160 These events represent 3% and 5% of the simulated  $B^+B^-$  and  $B^0\bar{B}^0$  background  
 2161 samples respectively. We apply a 50% systematic uncertainty on the value of the  
 2162 branching ratios of the relevant decays to account for potential mismodeling.

### 2163 5.7.8 Photon multiplicity correction

2164 Even though the selection on the ECL clusters used to compute the neutral ECL  
 2165 extra energy  $NE_{ECL}^{extra}$  and the photon multiplicity  $N_\gamma$  (subsubsection 5.4.1.1) is de-  
 2166 vised to minimize data-simulation disagreement, discrepancies are observed in these  
 2167 distributions. These discrepancies are expected to come mainly from background  
 2168 simulation, as they are seen in the sidebands described in Subsection 5.6.3 and are  
 2169 only minimal in the embedded samples (Subsection 5.6.1). Figure 5.20 shows the  
 2170 distributions of interest for the different samples.

2171

2172 In order to derive a correction, the sideband that best describes the background  
 2173 distribution in the signal search sample (on-resonance events passing the selection  
 2174 described up to Section 5.3, before the selection on the BDT output is performed)  
 2175 for both  $NE_{ECL}$  and  $N_\gamma$  is identified (Figure 5.21). The wrong  $B$ -meson charge  
 2176 sideband is chosen to derive the correction applied to the right  $B$ -meson charge  
 2177 sample while the particle ID sideband is used for validation.

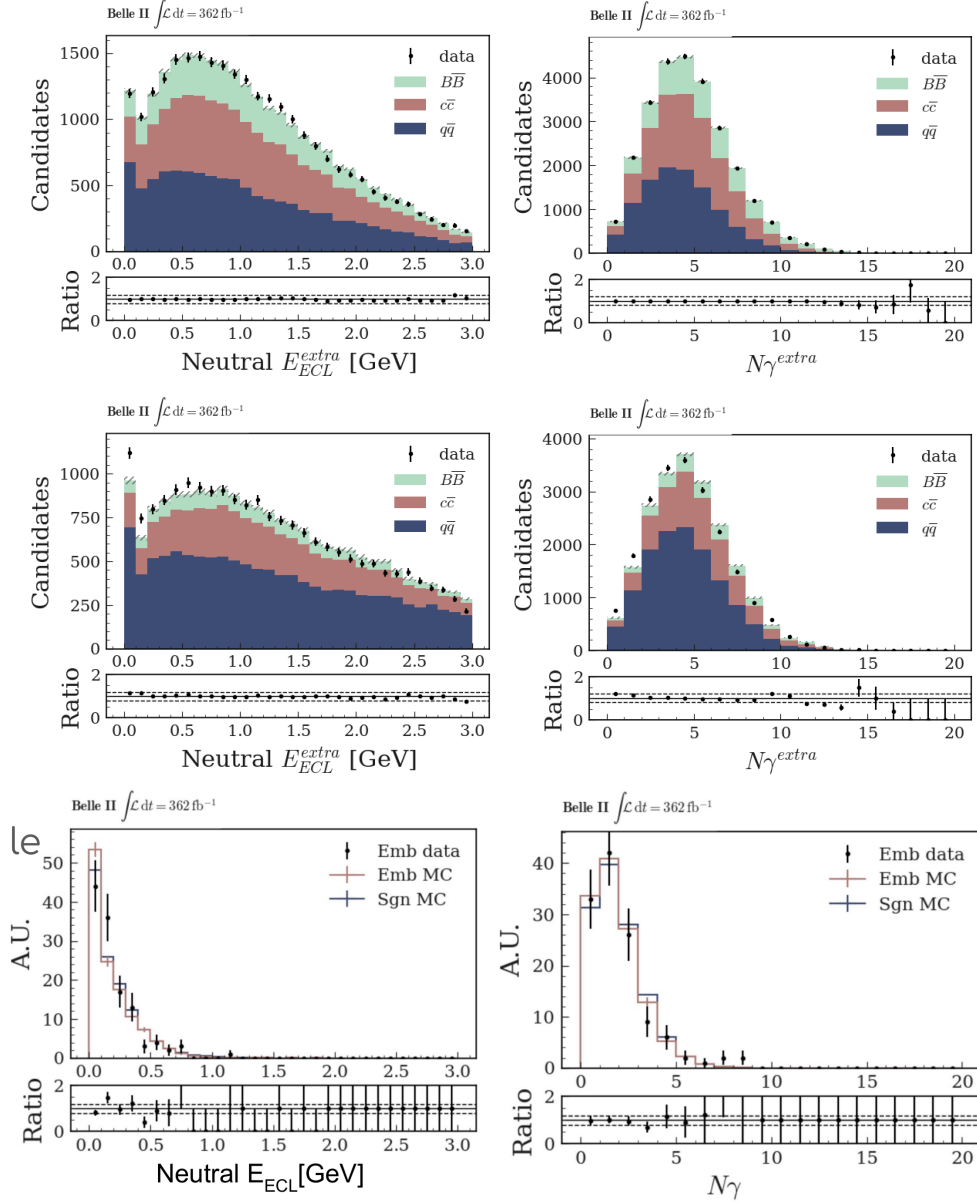

Figure 5.20: Distribution of the neutral ECL extra energy  $NE_{ECL}^{extra}$  and the photon multiplicity  $N_{\gamma}$  for the simulated (filled) and data (points) wrong  $B$ -meson charge sideband samples (top) and for the particle ID sideband samples (middle). The distribution for the same variables are shown for the embedded  $B^+ \rightarrow J/\Psi K^+$  simulated (red) and data (points) samples as well as for the signal (blue) simulated sample (bottom).

Figure 5.21: Distribution of the neutral ECL extra energy (left) and  $N_\gamma$  (right) for the particle ID (top, line histograms) and wrong  $B$ -meson charge (bottom, line histograms) sidebands. The filled histograms show the relevant distributions for the simulated background samples passing the signal selection, before the  $BDT$  output cut.

2178 For each  $N_\gamma$  value in the wrong  $B$ -meson charge sample, we compute the weight:

$$w_{N_\gamma} = \frac{n_D(N_\gamma)}{n_S(N_\gamma)}, \quad (5.12)$$

2179 where  $n_D(N_\gamma)$  and  $n_S(N_\gamma)$  correspond to the number of expected background events  
 2180 with  $N_\gamma$  extra photon candidates, in data and simulation respectively. The events  
 2181 in the signal region of the right  $B$ -meson charge sample are then weighted based on  
 2182 the associated  $N_\gamma$  value.

2183 The correction is then validated using the particle ID sideband sample. The sample  
 2184 is further divided into wrong  $B$ -meson charge and right  $B$ -meson charge. Then, the  
 2185 correction process is repeated as described before with the weight defined in [Equa-](#)  
 2186 [tion 5.12](#) computed using the wrong  $B$ -meson charge subsample of the particle ID  
 2187 sideband. The events in the right  $B$ -meson charge subsample are then reweighted  
 2188 accordingly. [Figure 5.22](#) shows the effect of the correction in this sample.

2189 Although an improvement is seen in the control sample after applying the correc-  
 2190 tion, some residual discrepancies persist. This indicates that the data-simulation

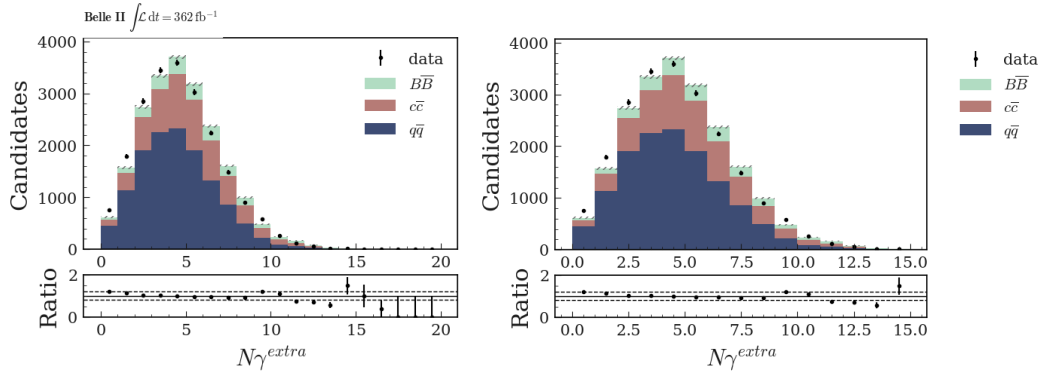

Figure 5.22: Distribution of the photon multiplicity  $N_\gamma$  for the right  $B$ -meson charge subsample of the particle ID sideband before (left) and after (right) correction. Distributions are shown for simulated background events (filled) and data (points).

2191 disagreement in the wrong  $B$ -meson charge sample might be slightly different with  
 2192 regards to the right  $B$ -meson charge sample. In order to account for this effect, we  
 2193 choose to assign an associated systematic uncertainty corresponding to  $\pm 100\%$  of  
 2194 the correction.

2195 Finally, even though the data-simulation agreement in the embedded samples seem  
 2196 acceptable, the size of the data sample is low which limits the comparison. To cover  
 2197 for a potential discrepancy, the simulated signal sample is also corrected using the  
 2198 method described previously. And the associated systematic is assigned.

2199

### 2200 5.7.9 Summary

2201 [Table 5.8](#) lists the different systematic uncertainty contributions to the statistical  
 2202 model.

Figure 5.23: Distribution of the likelihood-ratio test  $\Lambda_\mu$ , expecting a SM value for the  $B^+ \rightarrow B^+ \nu \bar{\nu}$  branching ratio. The different horizontal lines correspond (from top to bottom), to the  $5\sigma$ ,  $3\sigma$ , 90% CL and  $1\sigma$  levels.

## 2203 5.8 Results

2204 We now possess all the ingredients needed to measure the value of  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$ .  
 2205 We have defined the signal search region in Section 5.5 as well as the different sources  
 2206 of systematic uncertainties in Section 5.7. The expected yields in the signal region  
 2207 are computed for the four different event classes (signal,  $B\bar{B}$ ,  $c\bar{c}$  and  $q\bar{q}$ ) using the  
 2208 full simulated samples described in Section 5.1, weighted to match the on-resonance  
 2209 data sample integrated luminosity.

2210 At this point in time, the analysis is still kept blind (Section 4.7). Thus, we de-  
 2211 scribe in Subsection 5.8.1 how the branching fraction value for  $B^+ \rightarrow K^+ \nu \bar{\nu}$  is  
 2212 computed, providing an expected measurement based on simulated samples. In  
 2213 Subsection 5.8.2, the expected measurement is compared to previous results.

### 2214 5.8.1 Signal extraction setup

2215 From the likelihood  $\mathcal{L}(\mu, \theta)$ , the expected upper limit on the value of  $\mathcal{B}(B^+ \rightarrow$   
 2216  $K^+ \nu \bar{\nu})$  is computed as described in Section 4.6. Expecting SM value for  $\mathcal{B}(B^+ \rightarrow$   
 2217  $K^+ \nu \bar{\nu})$ , Figure 5.23 shows the distribution of the likelihood-ratio test  $\Lambda_\mu$  defined in  
 2218 Equation 4.26. From this, we extract the expected upper limit:

$$\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu}) < 2.3 \times 10^{-5} \quad (5.13)$$

2219 at 90% confidence level. The significance level  $\alpha_0$  of the associated signal strength  
 2220  $\mu$  is computed as:

$$\alpha_0 = \sqrt{2 \ln \mathcal{L}(\mu = 0) - 2 \ln \mathcal{L}(\mu = \mu_{min})}, \quad (5.14)$$

2221 we extract the significance  $\alpha_0 = 0.55$  to reject the null hypothesis.

Source	Affected category	Treatment	Size
Kaon-ID	sig, $B\bar{B}$ , cont	3 component-correlated	
tracking	sig	+ 1 uncorrelated	0.9%
signal efficiency	sig	normalization	16%

	sig, $B\bar{B}$	normalization-correlated	1.5%

Table 5.8: Summary of the systematic uncertainties treatment. The ‘‘cont’’ category includes both  $c\bar{c}$  and  $q\bar{q}$  samples.

Experiment	Uncertainty on $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu}) (\times 10^{-6})$
Belle semileptonic	5.7
Belle hadronic	16
BaBar semileptonic	8.0
BaBar hadronic	13.5
BaBar combined	6.5
Belle II inclusive	16
Belle II hadronic expected	9.5

Table 5.9: Measured uncertainties on the branching fraction for this and published results.

Experiment	Uncertainty on $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu}) (\times 10^{-6})$
Belle semileptonic	8.0
Belle hadronic	23
BaBar semileptonic	8.9
BaBar hadronic	15.0
BaBar combined	7.2
Belle II inclusive	6.4
Belle II hadronic expected	9.5

Table 5.10: Measured uncertainties on the branching fraction for this and published results scaled to the luminosity of  $362 \text{ fb}^{-1}$  assuming  $1/\sqrt{\mathcal{L}}$  dependence.

## 2222 5.8.2 Comparison with previous measurements

2223 An uncertainty on the value of the signal strength  $\mu$  can be derived from the statis-  
 2224 tical model. This allows to compute an uncertainty on the value of the branching  
 2225 fraction of the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay. Table 5.9 presents a comparison of the branch-  
 2226 ing fraction uncertainty from the previous analyses of Belle [63, 64], BaBar [62]  
 2227 and Belle II [65] with the expected uncertainty for this analysis. Table 5.10 pro-  
 2228 vides similar information, with uncertainties from the previous experiments scaled  
 2229 as  $\sqrt{\mathcal{L}/362 \text{ fb}^{-1}}$  to the luminosity of this analysis. For Belle, the uncertainties on  
 2230 the branching fraction are obtained using published information on the signal yield  
 2231 and signal selection efficiency.

2232 The expected preliminary results for this analysis are very competitive with  
 2233 previous publications. The main improvements compared to the previous Belle  
 2234 hadronically-tagged result come from a higher tagging efficiency and better perfor-  
 2235 mance of the final BDT selection.

2236

# Conclusion

2237

2238

2239

2240 This thesis has described the first search for the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay using a hadronic  
2241 tagging method in the Belle II experiment, as well the development of an algorithmic  
2242 method to improve the spatial resolution of the experiment's Silicon Vertex Detector.

2243

2244 Chapter 1 discussed how the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay is predicted in the Standard  
2245 Model of particle physics, operating through a suppressed flavour changing neutral  
2246 current quark transition, as well as how its branching fraction can be computed in  
2247 said model. In addition, possible beyond Standard Model contribution to this decay  
2248 have been described, showing how an experimental determination of the branching  
2249 fraction value can help to constrain new physics models.

2250

2251 Chapter 2 showed an overview of the experimental apparatus used to perform  
2252 the works presented. This apparatus consists in SuperKEKB accelerator, colliding  
2253 electron/positron at the  $\Upsilon(4S)$  resonance in order to produce pairs of  $B$ -mesons, as  
2254 well as the Belle II detector used to study said collisions.

2255

2256 Chapter 3 described the way the spatial resolution of Belle II's vertex detector  
2257 is estimated, as well as an algorithmic method, the *cluster unfolding*, designed to  
2258 correct for charge sharing between silicon strips. This method has been introduced  
2259 to improve the performances of the detector, as well as to reduce the discrepancies  
2260 seen in the spatial resolution estimation between data and simulation. This method  
2261 allows to improve the detector's spatial resolution by 5 to 15% for specific sensors.

2262

2263 Chapter 5 presented the full analysis developed to perform the search for the  
2264  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay using a data sample of  $362 \text{ fb}^{-1}$  equivalent integrated luminos-  
2265 ity at the  $\Upsilon(4S)$  resonance and  $42 \text{ fb}^{-1}$  collected 60 MeV below. The selection of  
2266 events of interest has been described, as well as the hadronic method employed to  
2267 reconstruct  $B$ -mesons in said events. The sanity of the analysis has also been tested  
2268 on several control samples, and the different systematic uncertainty contributions  
2269 to the expected measurement have been thoroughly evaluated.

2270 Given the available datasets, the analysis is expected to put an upper limit on the  
2271 value of the branching ratio  $\mathcal{B}(B^+ \rightarrow K^+ \nu \bar{\nu})$  at  $2.3 \times 10^{-5}$  at 90% confidence level.  
2272 The measurement is expected to be  $\sim 30\%$  more precise than the world leading mea-  
2273 surement for hadronically tagged searches for the  $B^+ \rightarrow K^+ \nu \bar{\nu}$  decay published by  
2274 the BaBar collaboration [62], and  $\sim 40\%$  more than the previous Belle collaboration  
2275 measurement [63].

2276

2277 Still, there remain many opportunities for the study of  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decays. New  
2278 experimental methods are currently developed which would benefit the searches for  
2279 these decays, such as the inclusive tagging method used by the Belle II collaboration  
2280 in the search for the  $B^+ \rightarrow K^+\nu\bar{\nu}$  decay using a reduced dataset of  $63 \text{ fb}^{-1}$  collected  
2281 at the  $\Upsilon(4S)$  resonance [65].

2282 The use of machine learning in tagging algorithms is also being studied, which could  
2283 yield higher efficiencies in the studies of such decays. In addition, the search for the  
2284 other  $B \rightarrow K^{(*)}\nu\bar{\nu}$  decay modes  $B^+ \rightarrow K^{*+}\nu\bar{\nu}$ ,  $B^0 \rightarrow K^0\nu\bar{\nu}$  and  $B^0 \rightarrow K^{*0}\nu\bar{\nu}$  is  
2285 also underway, using hadronic, semileptonic and inclusive tagging methods. Com-  
2286 bining future results will allow to better understand the Standard Model of particle  
2287 physics, as well as to constrain numerous new physics models.

2288

2289 Finally, in addition to improvement in methods, the new data planed to be  
2290 collected by the Belle II and LHCb experiments in the future will surely allow to  
2291 provide exciting flavour physics results.

# Résumé en Français

Mon travail de thèse s'est déroulé au sein de la collaboration Belle II, regroupant plus de 1000 membres issus de 27 pays.

Au cours de ma thèse, j'ai développé une méthode complète visant à analyser les données collectées par la collaboration Belle II, afin de mettre en évidence un processus physique jamais observé. De plus, j'ai également prit part au fonctionnement et à l'amélioration de l'expérience Belle II en participant à l'amélioration des performances de l'un des détecteurs utilisé au cours de la prise de données. Ces deux axes de recherche originaux sont détaillés ci-après.

## Recherche de la désintégration $B^+ \rightarrow K^+\nu\bar{\nu}$ au sein de l'expérience Belle II

La majeure partie de cette thèse est consacrée à la mesure de la désintégration  $B^+ \rightarrow K^+\nu\bar{\nu}$ . Ce processus est décrit par le Modèle Standard (MS) de la physique des particules avec un rapport d'embranchement  $\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu}) = (4.43 \pm 0.38) \times 10^{-6}$  [35]. Cette mesure est motivée d'une part par le fait que ce processus n'a jamais été mesuré et, d'autre part, car plusieurs modèles de Nouvelle Physique (NP, décrivant l'ensemble des théories non incluses dans le MS), prédisent des modifications du rapport d'embranchement du canal de désintégration  $B^+ \rightarrow K^+\nu\bar{\nu}$  [40, 41, 44–50].

Le fait que la désintégration  $B^+ \rightarrow K^+\nu\bar{\nu}$  n'ait à ce jour pas été observée peut être expliqué par son faible rapport d'embranchement ainsi que par les difficultés expérimentales liées à son observation. En effet, les deux neutrinos présents dans l'état final interagissent très faiblement avec la matière, ils sont donc dans les faits "invisibles" pour nos détecteurs. Afin de mesurer un processus physique rare et partiellement invisible, il est nécessaire de tirer avantage d'un dispositif expérimental spécifique: dans notre cas, l'expérience Belle II.

L'expérience Belle II est composée de l'accélérateur SuperKEKB, permettant la production de nombreuses collisions  $e^+e^-$  à une énergie de 10.58 GeV. SuperKEKB détient actuellement le record du monde de luminosité instantanée ( $4.7 \times 10^{34} \text{cm}^{-2}\text{s}^{-1}$ ) et a permis de collecter un échantillon de données correspondant à  $424 \text{fb}^{-1}$  entre 2019 et 2022. L'expérience Belle II est complétée par le détecteur Belle II construit autour du point de collision de SuperKEKB. Ce détecteur de forme cylindrique est formé de plusieurs couches de sous-détecteurs spécialisés, permettant de réaliser des mesures complètes des collisions produites (voir Figure 7.1). Ces sous-détecteurs sont, par ordre croissant de distance au point de collision:

- 2329 • Le détecteur à pixels (PXD), utilisé pour reconstruire les vertexs produits par  
2330 les collisions, est composé d'une couche de senseurs DEPFET. Une seconde  
2331 couche a été installée courant 2023).
- 2332 • Le détecteur de vertex à pistes de silicium (SVD). Ce détecteur est également  
2333 utilisé pour la reconstruction de vertexs ainsi que pour la trajectographie et  
2334 l'identification de particules et est composé de 4 couches de détecteurs à piste  
2335 de silicium.
- 2336 • La chambre à dérive (CDC) participe à la trajectographie et à l'identification  
2337 des particules. Elle consiste en un volume gazeux complété par de nombreux  
2338 fils métalliques servant à la détection de particules chargées électriquement.
- 2339 • Le détecteur de temps de propagation (TOP) situé sur la partie cylindrique du  
2340 détecteur Belle II et le détecteur de radiation Cherenkov à aerogel (ARICH)  
2341 situé aux extrémités axiales du détecteur forment le système d'identification  
2342 des particules.
- 2343 • Le calorimètre électromagnétique (ECAL), composé de cristaux de CsI(Tl)  
2344 permet de reconstruire les particules électriquement neutres.
- 2345 • Un aimant supraconducteur générant un champs magnétique de 1.5 T per-  
2346 met de modifier la trajectoire des particules chargées afin de mesurer leurs  
2347 impulsions.
- 2348 • Le détecteur de  $K_L^0$  et de muons, composé d'un sandwich d'épaisses couches  
2349 de fer et de chambres RPC, fini de compléter le détecteur Belle II.

2350 L'alliance du grand nombre de collisions  $e^+e^-$  produites par SuperKEKB, des per-  
2351 formances du détecteur Belle II et de son herméticité font de Belle II la seule expéri-  
2352 ence de physique des particules sur collisionneur de sa génération capable d'observer le  
2353 canal de désintégration  $B^+ \rightarrow K^+\nu\bar{\nu}$ . J'ai donc développé une chaîne d'analyse com-  
2354 plète en utilisant les outils de Belle II afin d'observer la désintégration  $B^+ \rightarrow K^+\nu\bar{\nu}$   
2355 pour la première fois en utilisant les données collectées avant l'été 2022.

2356 Cette analyse tire profit de l'algorithme de *Full Event Interpretation* (FEI) développé  
2357 par la collaboration Belle II [101]. L'énergie de collision de SuperKEKB étant fixée  
2358 à la valeur nécessaire à la production de la resonance  $\Upsilon(4S)$ , se désintégrant selon  
2359 le canal  $\Upsilon(4S) \rightarrow B\bar{B}$ , les évènements de collisions de signal sont composés de deux  
2360 mésons  $B$ , l'un ( $B_{sig}$ ) se désintégrant dans le canal  $B^+ \rightarrow K^+\nu\bar{\nu}$  tandis que l'autre  
2361 ( $B_{tag}$ ) se désintègre de façon aléatoire. Le but de l'algorithme FEI est de recon-  
2362 struire le  $B_{tag}$  selon la chaîne de désintégration la plus probable tirée d'une liste  
2363 de plus de 10000 chaînes possibles. Cet algorithme a été développé spécifiquement  
2364 pour l'étude de canaux de désintégrations impliquant des neutrinos. En effet, les  
2365 détails de la collision étant précisément connus, la reconsutruction du  $B_{tag}$  permet,  
2366 au travers de lois de conservations, d'accéder aux propriétés des neutrinos produits  
2367 (et échappant à la détection).

Figure 7.1: Vue schématique de l'accélérateur SuperKEKB (gauche) et du détecteur Belle II (droite). Adapté de [25].

2368 Mon analyse utilise un arbre de décision boosté (BDT) entraîné à différencier entre  
 2369 les événements de signal et de bruits de fond. Cet entraînement est effectué sur  
 2370 un échantillon simulé. Cette simulation reproduit les processus physiques issus des  
 2371 collisions ainsi que les performances du détecteur. Les événements de signal et de  
 2372 bruits de fond sont différenciés en se basant sur 12 variables. Les variables présen-  
 2373 tant le plus fort pouvoir de discrimination étant l'énergie mesurée dans l'ECAL et  
 2374 non associée au  $B_{tag}$  reconstruit ou au kaon issu de la désintégration du  $B_{sig}$ , et  
 2375 la somme de l'énergie et de l'impulsion manquantes dans l'évènement. Les autres  
 2376 variables utilisées rendent compte de la distribution dans l'espace des différentes  
 2377 particules produites dans l'évènement, ainsi que de la cinématique du  $B_{sig}$ .

2378 La structure du BDT est elle aussi optimisée, à l'aide du logiciel *optuna* [111], afin  
 2379 d'obtenir la classification la plus performante possible. Le BDT ainsi entraîné per-  
 2380 met une bonne séparation entre événements de signal et de bruits de fond, et le  
 2381 sur-entraînement du BDT est gardé à un niveau raisonnablement bas.

2382 Il est alors possible de définir une région de signal basée sur la distribution de la  
 2383 variable de sortie du BDT: pour chaque événement cette variable prend une valeur  
 2384 comprise entre 0 et 1: une valeur élevée traduit une forte probabilité que l'évènement  
 2385 en question soit un événement de signal. La région de signal est alors définie comme  
 2386 l'ensemble des événements ayant une valeur de sortie de BDT supérieure à 0.4. On  
 2387 s'attend dans cette région à trouver un maximum d'évènements de signal, tout en  
 2388 limitant la contamination des bruits de fond (Figure 7.2).

2389 À ce stade le comportement de l'analyse n'est estimé que sur des échantillons  
 2390 simulés, il est alors nécessaire de s'assurer que la simulation décrit les résultats  
 2391 mesurés de manière satisfaisante, tout en évitant d'étudier la région de signal dans  
 2392 les données, afin de ne pas introduire de biais dans la mesure. Pour ce faire, différents  
 2393 canaux de contrôles sont définis:

- 2394 • L'efficacité de la sélection pour le signal est difficile à estimer dans les données  
 2395 sans introduire de biais de mesure. Des événements partiellement simulés sont

Figure 7.2: Distributions de la valeur de sortie du BDT pour différents échantillons simulés. La figure de gauche montre l'ensemble de l'intervalle de définition de la variable tandis que la figure de droite correspond à la région de signal. Les distributions présentées correspondent au signal (violet) et aux évènements  $e^+e^- \rightarrow B\bar{B}$  (vert),  $e^+e^- \rightarrow c\bar{c}$  (rouge) et  $e^+e^- \rightarrow q\bar{q}$  (bleu).

2396 donc étudiés: des évènements de la forme  $e^+e^- \rightarrow \Upsilon(4S) \rightarrow B_{tag}B'_{sig}$ , avec  
 2397  $B'_{sig} \rightarrow K^+J/\Psi(\mu^+\mu^-)$  sont sélectionnés, la contribution du  $B'_{sig}$  est ensuite  
 2398 remplacée par la contribution de  $B_{sig} \rightarrow K^+\nu\bar{\nu}$  extraite d'un évènement de  
 2399 signal simulé. Cette procédure est appelée *embedding*.

2400 La procédure d'*embedding* est également appliquée à des évènements simulés  
 2401 comme vérification supplémentaire. Figure 7.3 montre la distribution de la  
 2402 valeur de sortie du BDT pour les différents échantillons considérés. Malgré  
 2403 des limitations liées à la taille de l'échantillon de données, la simulation du  
 2404 signal et l'efficacité de sa sélection semblent bien reproduire ce qui est observé  
 2405 dans les données.

- 2406 • La qualité de la simulation pour les évènements de type  $e^+e^- \rightarrow q\bar{q}$ , avec  $q$   
 2407 un quark  $u, d, s$  ou  $c$  est étudiée grâce à des données collectées avec une én-  
 2408 ergie de collision 60 MeV en dessous de l'énergie nécessaire à la production de  
 2409 la resonance  $\Upsilon(4S)$  (données non-résonnantes). Cet échantillon de données à  
 2410 l'avantage d'être totalement dépourvu de contributions de signal. Les distribu-  
 2411 tions des différents variables utilisées dans la selection sont comparées entre  
 2412 les données et les échantillons simulés. Un accord correct est observé. Une  
 2413 correction de la simulation est cependant développée afin d'améliorer la de-  
 2414 scription des données. Pour ce faire, une pondération est calculée pour chaque  
 2415 évènement simulé à partir de la valeur de sortie d'un BDT (nommé BDT<sub>c</sub>),  
 2416 entraîné sur les données non-résonnantes et sur les évènements  $e^+e^- \rightarrow q\bar{q}$   
 2417 simulés. Figure 7.4 montre l'impact de cette correction sur l'accord entre  
 2418 données et simulation.

2419 • Enfin, la qualité de la simulation pour les événements de bruits de fond de type  
 2420  $e^+e^- \rightarrow q\bar{q}$  et  $e^+e^- \rightarrow B\bar{B}$  est étudiée dans les données collectées à l'énergie  
 2421 de la résonance  $\Upsilon(4S)$ . Afin d'éviter une observation des événements de la  
 2422 région de signal, des échantillons sont définis en inversant certains critères de  
 2423 la sélection nominale de l'analyse (les autres critères sont gardés tels quels).  
 2424 Les deux échantillons ainsi construits sont: un échantillon pour lequel les  $B_{tag}$   
 2425 et  $B_{sig}$  reconstruits sont requis de posséder la même charge électrique (échan-  
 2426 tillon  $WC$ ) et un échantillon pour lequel la particule identifiée comme le kaon  
 2427 provenant du  $B_{sig}$  a une forte probabilité d'être un pion (échantillon  $KID$ ).  
 2428 **Figure 7.5** montre un désaccord entre données et simulation pour ces échan-  
 2429 tillons (tempéré par de conséquentes incertitudes statistiques liées à la taille  
 2430 des échantillons de données). Une incertitude systématique est alors estimée  
 2431 à partir de cette étude afin de couvrir de potentiels problèmes de simulation.

2432 Par la suite, plusieurs sources d'incertitudes systématiques sont identifiées et leur  
 2433 impact sur la mesure est estimé. Ces incertitudes sont d'origines diverses: inefficac-  
 2434 ités du détecteur, incertitudes théoriques liées aux prédictions du MS ou simulation  
 2435 des canaux de bruits de fond.

2436 Toutes les étapes nécessaires à la mesure de  $\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu})$  sont alors développées.  
 2437 Cependant, comme décrit ci-avant, cette analyse doit être validée par l'ensemble de  
 2438 la collaboration Belle II avant d'autoriser l'étude de la région de signal, afin d'éviter  
 2439 tout biais. Cette analyse est à ce jour en attente de cette validation. Il est cependant  
 2440 possible d'estimer sa sensibilité en se basant sur l'étude d'échantillons simulés. En  
 2441 supposant une valeur de  $\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu})$  égale à la valeur attendue dans le SM, il  
 2442 est possible d'extraire la limite supérieure:

$$\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu}) < 2.3 \times 10^{-5} \quad (7.1)$$

2443 pour un niveau de confiance de 90%.

2444 Ce résultat attendu est compétitif avec les tentatives de mesures de  $\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu})$   
 2445 menées par le passé par les collaboration Belle et BaBar [61–64], pourtant basées  
 2446 sur des échantillons jusqu'à deux fois plus conséquents que celui étudié ici. Ceci est  
 2447 expliqué par les performances du détecteur Belle II et de la sélection développée ici,  
 2448 comparées aux performances d'expériences plus anciennes.

## 2449 Amélioration de la résolution spatiale du détecteur de ver- 2450 tex de l'expérience Belle II

2451 Le détecteur de vertex à pistes de silicium (SVD) de l'expérience Belle II est un  
 2452 élément crucial du détecteur, contribuant à la trajectographie, à l'identification de  
 2453 particules et permettant la reconstruction des vertex de désintégration des partic-  
 2454 ules produites au sein de l'expérience. Le principe de mesure du SVD se base sur  
 2455 l'ionisation de pistes de silicium réparties sur quatre couches concentriques induite  
 2456 par le passage de particules chargées. Sur une couche et pour une particule donnée,

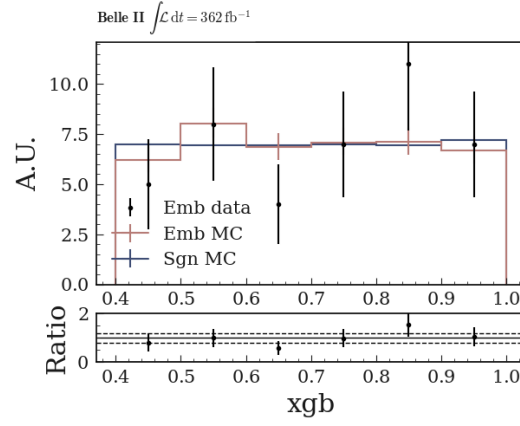

Figure 7.3: Distributions de la valeur de sortie du BDT dans la région de signal pour l'échantillon de signal simulé (bleu) ainsi que pour les échantillons ayant subi la procédure d'*embedding* (simulation en rouge et données en points).

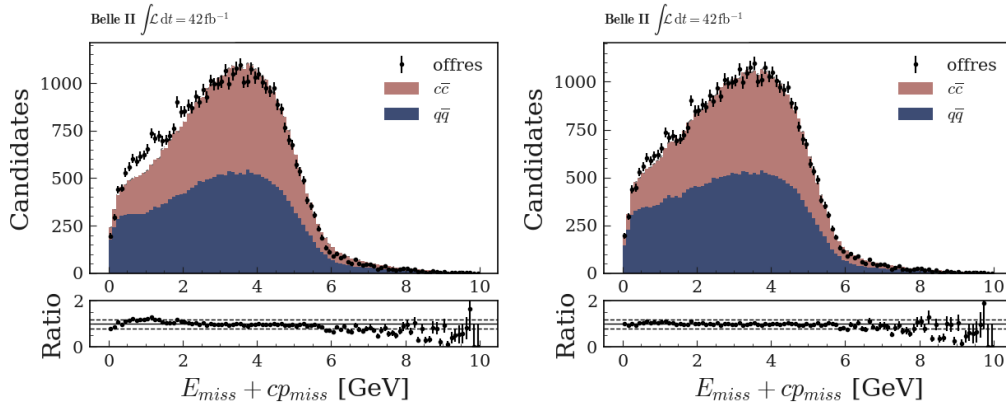

Figure 7.4: Distributions de la somme de l'énergie manquante pour les échantillons  $e^+e^- \rightarrow q\bar{q}$  simulés ainsi que pour les données non-résonnantes (points), avant (gauche) et après correction (droite).

Figure 7.5: (haut) valeur de sortie du BDT dans la région de signal pour les échantillons simulés après application de la sélection nominale (histogrammes pleins) et après les sélections modifiées pour éviter une contamination pour le signal (histogrammes en lignes). (bas) Comparaison entre données et simulations dans la région de signal après application de ces mêmes sélections modifiées. Les figures de gauche correspondent à l'échantillon *WC* tandis que les figures de droites correspondent à l'échantillon *KID*.

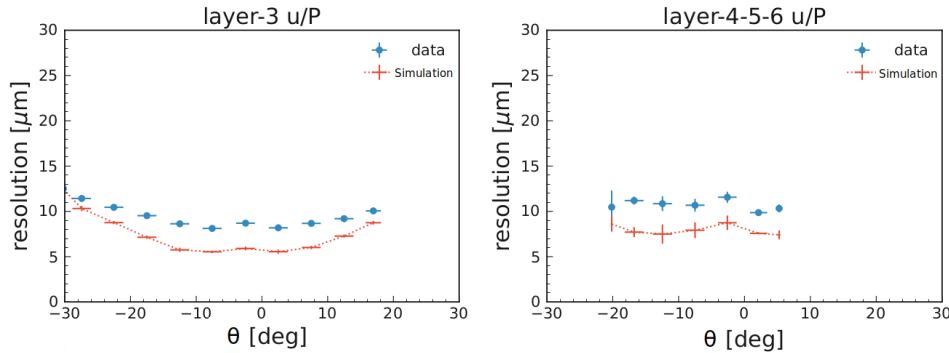

Figure 7.6: Comparaison entre données et simulation de l'estimation de la résolution spatiale en fonction de l'angle de la trajectoire de la particule incidente  $\theta$ .

2457 plusieurs pistes subissent cette ionisation autour du point de passage de la particule. Ces pistes sont alors regroupées en un amas servant à estimer la position de l'intersection entre la trajectoire de la particule et la couche. Plusieurs caractéristiques de l'amas peuvent être calculées (temps écoulé entre l'évènement de collision et la traversée de la couche par la particule, charge totale collectée par les pistes, position de l'amas).

2463 La position  $x_A$  de l'amas est calculée comme:

$$x_A = \frac{\sum_{i=0} x_i \times S_i}{\sum_{i=0} S_i} \quad (7.2)$$

2464 avec  $x_i$  la position de la piste  $i$  et  $S_i$  la charge collectée par la même piste.

2465 La position des différents amas est utilisée par les algorithmes de trajectographie, c'est pourquoi la mesure de cette position se doit d'être la plus précise possible. Cette précision est estimée par la résolution spatiale du détecteur, prenant en compte l'écart entre la position mesurée d'un amas et la position attendue de l'intersection entre la trajectoire de la particule et la couche portant l'amas (estimée grâce à la position des amas reconstruits sur les autres couches du détecteur) ainsi que l'erreur associée à la mesure de cet écart.

2472 La résolution spatiale du détecteur est estimée en utilisant les données collectées ainsi que des échantillons simulés (Figure 7.6). On observe alors un désaccord entre données et simulation, la résolution estimée à l'aide d'échantillons simulés étant systématiquement plus basse (simulation optimiste). J'ai alors mené un travail de recherche visant à déterminer de possibles causes expliquant ce désaccord.

2477 Des mesures effectuées sur le détecteur semblent indiquer un effet électronique menant à un biais dans la mesure du signal collecté par les différentes pistes. À cause de cet effet, la mesure de la charge collectée par une piste se voit biaisée à hauteur de 6% de la charge collectée par les pistes voisines. Figure 7.7 illustre cet effet qui semble systématique et affecte l'ensemble des pistes du détecteur.

2482 Afin de corriger ce biais j'ai développé une méthode algorithmique visant à découpler cet échange de charge apparent. Pour ce faire, une matrice  $M$  de taille  $n \times n$

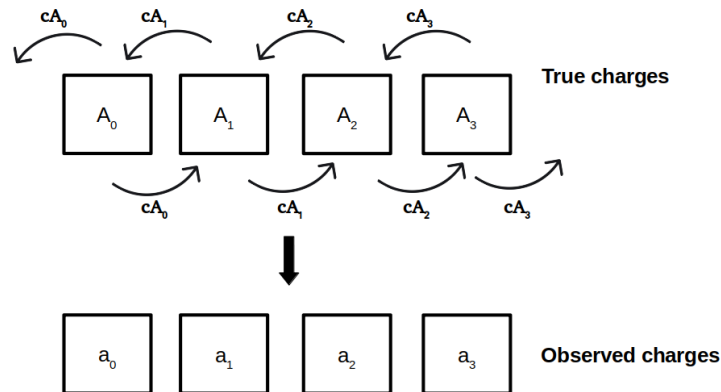

Figure 7.7: Représentation schématique de l'effet électronique biaisant la mesure de la charge collectée par les pistes du détecteur. La relation entre la charge réelle  $A_i$  collectée par la piste  $i$  et  $a_i$  la valeur observée biaisée par l'effet est illustrée.

2484 ( $n$  correspondant au nombre de pistes formant l'amas considéré) est définie comme:

2485

$$\begin{cases} M_{ij} = 1 - 2c & \text{if } i = j; \\ M_{ij} = c & \text{if } |i - j| = 1; \\ M_{ij} = 0 & \text{for all others } (i, j); \end{cases} \quad (7.3)$$

2486 où  $c = 0.06$  correspond à la fraction de charge collectée apparemment échangée entre  
2487 deux pistes adjacentes. Il devient alors possible d'estimer la valeur  $A_i$  réellement  
2488 collectée par la piste  $i$  à partir des charges collectées observée  $a_i$ ,  $a_{i-1}$  et  $a_{i+1}$ :

$$\begin{pmatrix} A_0 \\ A_1 \\ \dots \\ A_{n-1} \end{pmatrix} = M^{-1} \begin{pmatrix} a_0 \\ a_1 \\ \dots \\ a_{n-1} \end{pmatrix}. \quad (7.4)$$

2489 En appliquant cette correction, on observe une réduction du désaccord entre don-  
2490 nées et simulation dans l'estimation de la résolution spatiale FIGURE\*\*\*\*. Cette  
2491 correction est implémentée dans le système d'analyse central de la collaboration  
2492 Belle II.

2493 On s'attend à ce que le désaccord restant entre données et simulation soit dû à  
2494 une combinaison de plusieurs effets de faibles amplitude, rendant leur identification  
2495 complexe.

## 2496 Conclusion

2497 La mesure du rapport d'embranchement de la désintégration  $B^+ \rightarrow K^+\nu\bar{\nu}$  est au  
2498 centre du programme de physique de l'expérience Belle II. En effet, Belle II est la  
2499 seule expérience de sa génération à pouvoir mesurer cette observable, de plus, ce  
2500 résultat est attendu par l'ensemble de la communauté de la physique des saveurs,  
2501 car de nombreux modèles d'extension du Modèle Standard de la physique des par-  
2502 ticules prédisent des modifications de  $\mathcal{B}(B^+ \rightarrow K^+\nu\bar{\nu})$ . Au cours de ma thèse j'ai  
2503 développé une analyse complète visant à permettre la première observation de cette  
2504 désintégration, et j'ai eu l'occasion de valider cette méthode sur des événements  
2505 simulés.

2506 De plus, j'ai développé et implémenté dans le système d'analyse central de la col-  
2507 laboration une méthode permettant de corriger l'estimation de la résolution spatiale  
2508 du détecteur de vertex de Belle II.

APPENDIX D

2532

# Background composition in the signal region

2533

2534

---

2535 Several particle classes are defined to categorize  $B$ -meson decays, in order to better  
2536 study the  $B\bar{B}$  contribution to the analysis. Here, we show how these classes are  
2537 built.

Class	Particles
D	$D^+, D^0, D_0^*(2300)^+, D_0^*(2300)^0, D^*(2010)^+, D^*(2007)^0, D_1(2420)^+, D_1(2420)^0, 20413, D_1(2430)^0, D_2^*(2460)^+, D_2^*(2460)^0, D_s^+, D_{s0}^*(2317)^+, D_s^{*+}, D_{s1}(2536)^+, D_{s1}(2460)^+, D_{s2}^*(2573)^+$
$\ell$	$e^-, \mu^-$
$\tau$	$\tau^-$
$\nu$	$\nu_e, \nu_\mu, \nu_\tau$
$n\pi$	$\pi^0, \pi^+, a_0(980)^0, a_0(980)^+, \pi(1300)^0, \pi(1300)^+, a_0(1450)^0, a_0(1450)^+, \pi(1800)^0, \pi(1800)^+, \rho(770)^0, \rho(770)^+, b_1(1235)^0, b_1(1235)^+, a_1(1260)^0, a_1(1260)^+, \pi_1(1400)^0, \pi_1(1400)^+, \rho(1450)^0, \rho(1450)^+, \pi_1(1600)^0, \pi_1(1600)^+, a_1(1640)^0, a_1(1640)^+, \rho(1700)^0, \rho(1700)^+, a_2(1320)^0, a_2(1320)^+, \pi_2(1670)^0, \pi_2(1670)^+, a_2(1700)^0, a_2(1700)^+, \rho_3(1690)^0, \rho_3(1690)^+, a_4(1970)^0, a_4(1970)^+, \eta, \eta'(958), f_0(500), f_0(980), \eta(1295), f_0(1370), \eta(1405), \eta(1475), f_0(1500), f_0(1710), \omega(782), \phi(1020), h_1(1170), f_1(1285), h_1(1415), f_1(1420), \omega(1650), \phi(1680), f_2(1270), f_2'(1525), \eta_2(1645), f_2(1950), f_2(2010), f_2(2300), f_2(2340), \omega_3(1670), \phi_3(1850), f_4(2050)$
$c\bar{c}$	$\eta_c(1S), \chi_{c0}(1P), \eta_c(2S), J/\psi(1S), h_c(1P), \chi_{c1}(1P), \psi(2S), \psi(3770), \psi(4040), \psi(4160), \psi(4415), \chi_{c2}(1P), \chi_{c2}(2P)$
Hadrons	$K_L^0, K_S^0, K^0, K^+, K_0^*(700)^0, K_0^*(700)^+, K_0^*(1430)^0, K_0^*(1430)^+, K(1460)^+, K(1830)^+, K_0^*(1950)^+, K^*(892)^0, K^*(892)^+, K_1(1270)^0, K_1(1270)^+, K_1(1400)^0, K_1(1400)^+, K^*(1410)^0, K^*(1410)^+, K_1(1650)^0, K_1(1650)^+, K^*(1680)^0, K^*(1680)^+, K_2^*(1430)^0, K_2^*(1430)^+, K_2(1580)^+, K_2(1770)^0, K_2(1770)^+, K_2(1820)^0, K_2(1820)^+, K_2^*(1980)^0, K_2^*(1980)^+, K_2(2250)^+, K_3^*(1780)^0, K_3^*(1780)^+, K_3(2320)^+, K_4^*(2045)^0, K_4^*(2045)^+, K_4(2500)^+, \pi^0, \pi^+, a_0(980)^0, a_0(980)^+, \pi(1300)^0, \pi(1300)^+, a_0(1450)^0, a_0(1450)^+, \pi(1800)^0, \pi(1800)^+, \rho(770)^0, \rho(770)^+, b_1(1235)^0, b_1(1235)^+, a_1(1260)^0, a_1(1260)^+, \pi_1(1400)^0, \pi_1(1400)^+, \rho(1450)^0, \rho(1450)^+, \pi_1(1600)^0, \pi_1(1600)^+, a_1(1640)^0, a_1(1640)^+, \rho(1700)^0, \rho(1700)^+, a_2(1320)^0, a_2(1320)^+, \pi_2(1670)^0, \pi_2(1670)^+, a_2(1700)^0, a_2(1700)^+, \rho_3(1690)^0, \rho_3(1690)^+, a_4(1970)^0, a_4(1970)^+, \eta, \eta'(958), f_0(500), f_0(980), \eta(1295), f_0(1370), \eta(1405), \eta(1475), f_0(1500), f_0(1710), \omega(782), \phi(1020), h_1(1170), f_1(1285), h_1(1415), f_1(1420), \omega(1650), \phi(1680), f_2(1270), f_2'(1525), \eta_2(1645), f_2(1950), f_2(2010), f_2(2300), f_2(2340), \omega_3(1670), \phi_3(1850), f_4(2050), p, n, \Delta(1232)^{++}, \Delta(1232)^+, \Delta(1232)^0, \Delta(1232)^-, \Lambda, \Sigma^+, \Sigma^0, \Sigma^-, \Sigma(1385)^0, \Sigma(1385)^-, \Xi^0, \Xi^-, \Xi(1530)^0, \Xi(1530)^-, \Omega^-$
